ABSTRACT

Context. Flares can help us trace magnetic activity because are bright and high-contrast on low mass stars.

Aims. This study aims to quantify flaring activity on these stars as a function of mass and age.

Methods. We automatically detected flares in K2 time-domain photometry, using the open-source software K2SC to remove instrumental and astrophysical variability from K2 light curves. We used injection and recovery of synthetic flares to assess detection thresholds, time sampling and de-trending effects on the inferred flare energies. With additional data from the full K2 archive we added stars with a larger variety of ages and spectral types to the analysis of the previous study (Ilin et al. 2019). We compared previous results from the Pleiades and Praesepe to the flare frequency distributions (FFDs) in M35 and the Hyades, respectively. Ruprecht 147 filled in the age gap at 2.5 Gyr between the aforementioned young clusters and the solar age cluster M67.

Results. We find that the flare production mechanism is similar for the entire parameter space, following a power law relation with exponent $\alpha \approx 2$, but the flaring frequencies depend on both mass, and age. We discuss X and Y.

Key words. Methods: data analysis, Stars: activity, Stars: flare, Stars: low-mass

1. Introduction

Flares are explosions on stellar surfaces with a complex spatio-temporal and energetic phenomenology. We know that flares are magnetic re-connection events that lead to a change in field line topology and subsequent energy release (Priest & Forbes 2002). We can observe flares in nearly all electromagnetic bands, from radio to X-rays, and on all stars that possess a convection zone. From late F type stars to ultracool dwarfs (Gizis 2013). But even with continuous monitoring at high temporal resolution, the random occurrence of solar flares makes them costly observing targets, especially in coordinated multi-band observations. In integrated light, most solar flares have a far too low contrast and intensity to be observable. Stellar flares on cool stars have two advantages in this respect. They are often bright, enhancing stellar flux by up to several orders of magnitude, and they typically exhibit blackbody emission at temperatures significantly higher than their stars' photospheres. With the evidence that the physical processes that cause flares on the Sun and other stars are the same (Karoff 2016), solar and stellar flares can inform each other (Shibayama et al. 2013). Inconsistencies in extrapolations from solar to stellar conditions (Aarnio et al. 2011; Aarnio et al. 2012; Drake et al. 2012; Alvarado-Gómez et al. 2018). Large surveys like Kepler and TESS enable statistical flare studies of stars that were not pre-selected for their activity (Walkowicz et al. 2011). Statistical studies of stellar flaring activity can help us understand the underlying physical processes CITE stellar surface magnetic fields, starspots (Davenport 2015; Howard

et al. 2019b), how flares relate to stellar angular momentum evolution (Mondrik et al. 2019; Howard et al. 2019b), how they affect the atmospheres of exoplanets (Lecavelier des Etangs et al. 2012; Loyd et al. 2018; Tilley et al. 2019; Howard et al. 2019a), and inform galactic archaeology (Howard et al. 2019a). Basic parameters that affect flaring behaviour on stars are their masses, and ages. Ages can be controlled for in coeval groups of stars, and flaring-age studies in binaries showed consistency in activity for both components in the majority of targets (Lurie et al. 2015; Clarke et al. 2018). Open clusters present other coeval groups of stars with well-determined ages. Ilin et al. (2019) (hereafter PaperI) investigated the flaring activity of late-K to mid-M dwarfs in three open clusters (OCs), the Pleiades, Praesepe, and M67, using K2 time domain photometry. They analysed the flare frequency distributions (FFDs), with respect to different masses and cluster ages. For the cluster members, the light curves revealed that their flaring activity declines both with age and mass. The decline is faster for higher mass stars. Recently, Davenport et al. (2019) put forward an empirical parametrization of this flaring-mass-age relation based on FFDs. The present study aims to extend the results in PaperI to the age of Ruprecht 147 (2.5 Gyr), and both higher and lower masses than in the previous study. We also test the previous results from the Pleiades on M35, and the results from Praesepe on the Hyades, as both OC pairs have approximately the same ages. Because the Kepler satellite retired in fall 2018, we can now use the complete K2 data set, and supplement all three OCs in PaperI with additional light curves. Additionally, we use high quality K2 light curves available for M67 (Nardiello et al. 2016) and M35 (Soares-Furtado et al. 2017). We discuss our results with

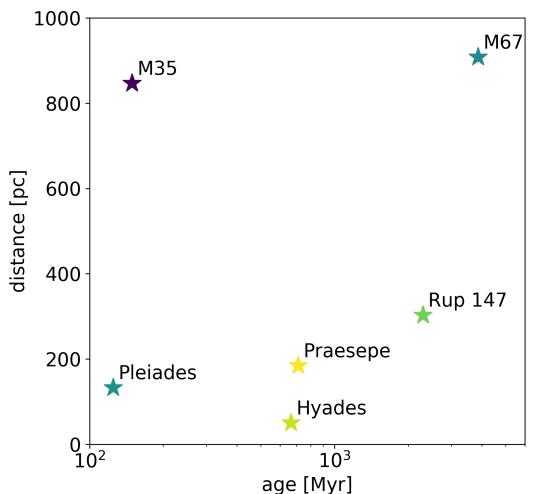

Fig. 1. The values for age, metallicity, and distance are approximate values from a compilation of existing literature, see Appendix ??.

respect to potential breaks in the power law distribution at high energies. Finally, we use the results to test the parametrizability in Davenport et al. (2019).

2. Data

Our main data are K2 target pixel files that were provided by the Kepler archives hosted at MAST, and light curves derived from them (Aigrain et al. 2016; Soares-Furtado et al. 2017; Vinícius et al. 2018). To assign T_{eff} to the targeted stars we used multi-band photometry obtained from Tycho, UCAC4, 2MASS, PanSTARRS, and Gaia catalogs. To assign ages to the targeted stars OC membership information was compiled from the literature. An overview over the cluster sample is presented in Table ?? and illustrated in Figure 1.

2.1. K2 light curves

The Kepler (Koch et al. 2010) spacecraft finished its follow-on mission K2 (Howell et al. 2014) in September 2018, after having completed nearly 20 80-day observing campaigns. Even though Kepler and K2 data are used in more than 2 400 publications to date, the public archive can still be considered understudied (Barentsen et al. 2018). In this spirit we took up the analysis of about 4 000 Kepler target pixel files that each contain up to 80 days of 30 min cadence observations in white light ($4, 200 - 9, 000 \text{ \AA}$). We also used light curves extracted from the K2 C0 super stamp. A super stamp is an aggregated set of typical Kepler postage stamps placed over a densely populated field, that also covers M35 (Soares-Furtado et al. 2017).

As K2 was conducted on the two-wheeled Kepler satellite, it was subjected to substantial drift motion (spacecraft roll, Van Cleve et al. 2016) and had an overall reduced pointing accuracy. To mitigate these effects, various solutions were developed (Vanderburg & Johnson 2014; Aigrain et al. 2016; ?; Luger et al. 2018)

2.2. Membership matching

We obtained membership information from multiple catalogs for each cluster. We cross-matched these catalogs on RA and

declination within 3 arcsec. The resulting target lists were used to search the K2 archive, or were matched to the catalogs of extracted light curves from crowded fields in the case of M35 (Soares-Furtado et al. 2017) and M67 (Nardiello et al. 2016).

One part of the membership catalogs provided membership probabilities (Douglas et al. 2014; Bouy et al. 2015; Cantat-Gaudin et al. 2018; Olivares et al. 2018; Reino et al. 2018; Gao 2018; Olivares et al. 2019). For the other part no probability was provided (Rebull et al. 2016a; Douglas et al. 2017; Gaia Collaboration et al. 2018a), or qualitative classifiers were given (Curtis et al. 2013; Gonzalez 2016; Rebull et al. 2017). In the latter cases we assigned approximate probabilities anchored to the set threshold for inclusion into our final sample. Absence in a catalog did not decrease the likelihood of membership, as each catalog shows different selection biases which we did not address in this study. We set the threshold mean membership probability p for a target in our sample to 0.8.

2.3. Open Clusters

We studied flaring activity in the low mass stars in six open clusters spanning from ZAMS to solar age. Table 1 provides an overview over the final sample. The literature overview of age, distance, and metallicity determinations is given in Table ?? in the Appendix. Membership probability histograms of the final sample are displayed in Figure ??.

2.3.1. Pleiades

The Pleiades, a nearby ZAMS cluster, were observed in Campaign 4, and were treated in PaperI. We include the cluster in this work for completeness and to illustrate improvements to (PaperI). We revisited the memberships from Rebull et al. (2016a), which were your in the previous work, and merged them with lists of members determined by Olivares et al. (2018); Gaia Collaboration et al. (2018a); and Cantat-Gaudin et al. (2018).

2.3.2. M35

M35 is a ZAMS cluster 900 pc away, observed during Campaign 0 in K2. We merged membership lists from Cantat-Gaudin et al. (2018); Gaia Collaboration et al. (2018a); and Bouy et al. (2015). There are only five K2 light curves, but we identified multiple additional members with publicly available¹ light curves obtained from Soares-Furtado et al. (2017). They used an image subtraction technique in the campaign's super stamps, a self flat-fielding de-trending inspired by K2SFF (Vanderburg & Johnson 2014), and a trend-filtering algorithm developed by Kovács et al. (2005). We preferred PSF photometry in cases where both aperture K2 and PSF LCs were available. We took the raw extracted PSF light curves and de-trended them using K2SC.

2.3.3. Hyades

The Hyades are a 0.6 Gyr old OC observed during Campaigns 4 and 13 with K2. It is about as old as Praesepe. We merged membership tables obtained from Douglas et al. (2014); Reino et al. (2018); and Gaia Collaboration et al. (2018a).

Table 1. Open clusters.

cluster	<i>n</i>	LCs	SLCs	LLCs	PSF LCs	age[Myr]	distance[pc]	[Fe/H]
Pleiades	2033	944	33	911	0	125		
M35	1614	5	0	5	158			
Hyades	655	301	42	259	0			
Praesepe	1281	2500	68	2432	0			
Rup 147	213	97	25	72	0			
M67	1344	1141	118	1023	1019			

Notes. *n* is the approximate number of members with $p > 0.8$. LCs, SLCs, LLCs, and PSF LCs denote the number of available light curves, short cadence light curves, long cadence light curves, and PSF de-detrended light curves, respectively. The values for age, [Fe/H], and distance are approximate values from a comparison of existing literature, detailed in Appendix ??.

149 2.3.4. Praesepe

150 Praesepe appeared in Campaign 5, and was previously treated
151 in PaperI. It was then observed again during Campaign 13. We
152 revisited the memberships obtained by Douglas et al. (2014), and
153 matched them to the members identified in Douglas et al. (2017)
154 Rebull et al. (2017); Cantat-Gaudin et al. (2018); and Gaia Col-
155 laboration et al. (2018a).

191 used the average extinction value of the respective cluster. We
192 accounted for extinction in Gaia BP and RP using the reddening
193 $E(B_P - R_P)$ derived from Gaia photometry and parallax from
194 Gaia DR2 (Andrae et al. 2018). We dropped targets that were
195 too bright (Kepler magnitude $K_p \leq 9$).
196

156 2.3.5. Ruprecht 147

157 Ruprecht 147 is a 2.5 Gyr old OC observed during Campaign 5
158 with K2. We used the mean membership probabilities obtained
159 from a number of studies (Curtis et al. 2013; Cantat-Gaudin et al.
160 2018; Olivares et al. 2019) combined with the members found
161 by Gaia Collaboration et al. (2018a) to identify the most likely
162 members.

197 2.4.2. Effective temperatures

163 2.3.6. M67

164 M67 is a solar-age, solar metallicity OC about 900 pc away.
165 Multiple members were observed during Campaign 5, and visited in Campaigns 16 and 18. We did not find any flares in
166 M67 in Campaign 5 (PaperI) observing the members identified
167 by Gonzalez (2016). The recent campaigns brought both additional observations, and entirely new targets to the sample. We
168 merged the members from Gonzalez (2016) with a recent study
169 based of Gaia DR2 data (Gao 2018). Additionally, we obtained
170 PSF-detrended light curves for Campaign 5 from Nardiello et al.
171 (2016).

198 We applied several methods and color-temperature relations
199 (CTRs) to determine robust T_{eff} . We used CTRs from Boyajian et al. (2013) and Mann et al. (2016) (erratum to Mann et al. 2015), and T_{eff} derived from Gaia DR2 using the StarHorse algorithm (Queiroz et al. 2018) and inferred from Gaia DR2 using the Apsis pipeline (Bailer-Jones et al. 2013; Andrae et al. 2018).
200 Boyajian et al. (2013) determined CTRs from a range of interferometrically characterized stars using $g - z$, $g - i$, $g - r$,
201 $g - J$, $g - H$, and $g - K$ colors from SDSS and Johnson magnitudes for A to K stars. Their sample is centered on solar metallicity, so we constrained the use of these CTRs to stars with
202 $-0.25 < [\text{Fe}/\text{H}] < 0.25$. We transformed 2MASS JHK to $J - H$,
203 $H - K$, and $J - K$ in the Johnson system as the authors from 2MASS to the Bessel-Brett system (Carpenter 2001), and from Bessel-Brett to Johnson using the relations in Bessell & Brett (1988).

204 Mann et al. (2015) provide CTRs from absolutely calibrated
205 spectra to which they fitted atmospheric models to obtain T_{eff} .
206 Alternatively, they determined T_{eff} from long-baseline optical
207 interferometry measurements using the bolometric flux. Among
208 others, they note transformations for SDSS/2MASS $r - z$ and
209 $r - J$, or Gaia $BP - RP$ where extra information can be added
210 from metallicity or 2MASS $J - H$. The relations in Mann et al.
211 (2015) are only valid if metallicity is sufficiently close to solar,
212 which is satisfied for all clusters in this paper (see Table ??).
213 M35 may be an exception to this rule.

214 We supplemented our estimates with T_{eff} estimates from Anders et al. (2019) who used the StarHorse pipeline (Queiroz et al. 2018) on Gaia DR2.

215 Gaia DR2 published effective temperatures for over 160 million sources (Gaia Collaboration et al. 2018b). The typical uncertainty is quoted at 324 K, but it is lower for stars above ~ 4100 K and below ~ 6700 K, so that we adopt 175 K which is above the quoted root-median-squared error in this T_{eff} range (Andrae et al. 2018), and use provided values only in this range.

216 Empirical CTRs suffer from systematic errors that stem both
217 from the different methods applied, and from sample selection
218 biases. We used as many empirical relations as possible in their
219 appropriate ranges to obtain multiple T_{eff} estimates from which
220 we then drew a more reliable median value. Targets that were
221

174 2.4. Effective temperatures, stellar radii, and luminosities

175 2.4.1. Photometry and extinction correction

176 We determined effective temperatures T_{eff} using broadband
177 photometry the Two Micron All Sky Survey (2MASS; Skrutskie
178 et al. 2006), the Panoramic Survey Telescope and Rapid
179 Response System (Pan-STARRS) Data Release 1 (Chambers et al.
180 2016), and Gaia DR2 (Gaia Collaboration et al. 2018b). We
181 applied quality cuts to 2MASS, Pan-STARRS DR1, and Gaia DR2
182 data, as described in Appendix ??, and removed foreground
183 stars using Gaia DR2 parallaxes. We corrected the 2MASS
184 and PanSTARRS photometry in M35, M67, and Ruprecht
185 147 for extinction using the most recent version (Green et al.
186 2019) of the dustmaps package that provides 3D dust maps
187 derived from 2MASS and PanSTARRS photometry together
188 with Gaia distances (Green et al. 2018). If there was no
189 parallax available we used the cluster median distance instead.
190 If an extinction value was not available for a given star

lacking sufficient photometric data to derive T_{eff} , or were too hot to be expected to have a convective envelope ($T_{\text{eff}} \geq 7000$ K), were flagged accordingly, and removed from the sample. We dropped all targets where the uncertainty on the weighted mean T_{eff} was greater than 10%. Only targets that were assigned a T_{eff} were searched for flares.

2.4.3. Stellar radii

We used a catalog of empirically characterised stars (Yee et al. 2017) to derive R_* from T_{eff} (Fig. 4). Yee et al. (2017) collected 404 stars with high-resolution spectra from the literature, and own observations of mid to late K-dwarfs, spanning low mass stars from 7000 K down to 3000 K. For these stars, the resulting catalog is accurate to 100 K in T_{eff} , 15 % in R_* , and 0.09 dex in [Fe/H]. We interpolated between stars from the catalog to our derived T_{eff} , and propagated the resulting scatter to the uncertainty in R_* if $T_{\text{eff}} > 3500$ K. For stars with $T_{\text{eff}} < 3500$ K we used $T_{\text{eff}} - R_*$ relations derived by (Mann et al. 2015, 2016).

2.4.4. Spectra

We assigned spectra to our targets from the SpecMatchEmp Yee et al. (2017) and the FlareSpecPhot libraries (Schmidt 2014; Kirkpatrick et al. 2010; Burgasser et al. 2007, 2008, 2010, 2004; Cruz et al. 2004; Burgasser & McElwain 2006; Rayner et al. 2009; Doi et al. 2010; Filippazzo et al. 2015; Cruz et al. 2003; West et al. 2011; Bochanski et al. 2010, 2007; Schmidt et al. 2010, 2015, 2014; Mann et al. 2015). When a spectrum was available for the derived spectral type in FlareSpecPhot, we preferred it over SpecMatchEmp, which was the case for all stars cooler than M0, where we mapped spectral type to effective temperature as appears in Pecaut & Mamajek (2013). We then combined stellar radii R_* , T_{eff} , and spectra to projected bolometric luminosities $L_{\text{bol},*}$, and projected luminosities in the Kepler band $L_{Kp,*}$ (Shibayama et al. 2013; Ilin et al. 2019). Uncertainties $L_{Kp,*}$ ranged from 9 % to 52 % with a median value of 17 %.²⁹⁴

3. Methods

We detected flare candidates automatically, and validated the by eye. We attempted to assign recovery probabilities and corrected for sampling effects using injection/recovery tests but the procedure was not scalable due to computational costs. We performed injection recovery on a handful of example light curves to see that de-trending and intrinsic light curve properties smear out the ED recovery with varying distributions that add an uncertainty of about 30%. Most of the candidates are expected to have a complex shape that deviates from the classical flare template. The validation yielded an estimate on the uncertainty on the energy released in the Kepler band. The frequency distribution of these flare energies are believed to follow a power law that spans multiple orders of magnitude. We adopted this model, and used two different Maximum Likelihood estimators to obtain the power law exponents. We tested the best fit parameters with the Kolmogorov-Smirnov test, and probed possible truncation of the power law relation with an exceedance test.

3.1. Flare finding

We used the open source software AltaiPony² to automatically detect and characterize flares in our sample. The code base

lies on K2SC³ (Aigrain et al. 2016) to remove instrumental and astrophysical variability from K2 light curves. We did not use the pre-detrended light curves available on MAST, but used K2SC to derive our own, because we clipped outliers at 3σ iteratively, as compared to the original work, where outliers were clipped at 5σ (Aigrain et al. 2016).

After de-trending, the flare finder algorithm looked for continuous observing periods, defined as being longer than 10 data points at a minimum cadence of 2 h. All further routines were run on these observing periods. The finder iteratively clipped excursions from the median value at 3σ rolling window noise above median plus uncertainty given from K2SC de-trending. After each iteration, outliers were cut down to the current median value. Either after convergence, or 50 iterations, the resulting median value was adopted. With this median as quiescent flux, flare candidates were identified with the same procedure as during the median value calculation, but now we additionally required at least three consecutive data points to fulfil the σ -criterion. Flare candidates were merged into single candidate events if they were no more than three data points apart. For each of these candidates occurrence time, amplitude and equivalent duration (ED) was returned.

The Kepler flare sample has shown to be difficult to treat in a fully automated way. Without manual vetting, the event samples remain significantly contaminated (Yang & Liu 2019).

ED is the area between the LC and the quiescent flux, that is, the integrated flare flux divided by the median quiescent flux F_0 of the star, integrated over the flare duration (Hunt-Walker et al. 2012):

$$ED = \int dt \frac{F_{\text{flare}}(t)}{F_0}. \quad (1)$$

ED is a quantity independent of calibration and distance that is suited to compare flaring activity on stars where these properties are uncertain. It describes the time during which a star releases as much energy as the flare itself. This time can be shorter or longer than the actual flare duration.

The uncertainty in ED depends on the light curve noise properties, time sampling, and other intrinsic characteristics. Moreover, K2SC de-trending and the flare finding procedure introduce additional uncertainty that dominates the photometric noise. Carrying out injection and recovery that takes into account the effect of GP regression that underlies K2SC. We only performed injection-recovery on a small number of light curves with flares to estimate the .

3.2. Kepler flare energies

(see PaperI for details).

Multiband time resolved observations of active M dwarfs have shown that continuum flux accounts for the majority of the energy radiated by flares (Kowalski et al. 2013). The effective temperature of this blackbody, however, varies by a great degree, with, to date, no robust predictor of that temperature:

While solar flares are relatively cool, with $T_{\text{eff}} \approx 5000 - 7000$ K (Kleint et al. 2016; Kerr & Fletcher 2014; Watanabe et al. 2013; Namekata et al. 2017), SEDs of stellar flares tend to be blue (?). At least one M dwarf flare reached 40 000 K as seen in FUV spectra (Froning et al. 2019), and most events exhibit temperatures of about 9 000 – 10 000 K (Hawley & Fisher 1992; Kretzschmar 2011; Shibayama et al. 2013). A dependence of flare temperature on

² <https://github.com/ekaterinailin/AltaiPony>

³ <https://github.com/OxES/k2sc>

318 stellar age, or mass, or both, will enter our analysis if we attempt
 319 to quantify bolometric flare energy. At about 6 200 K, the Kepler
 320 pass band captures the largest flux fraction, at 10 000 K 72 %,
 321 at 40 000 K only 4% of this value is transmitted. Another effect
 322 is that flares of equal flare energy but hotter SED would not be
 323 seen in the Kepler band at all.

324 We propagated the uncertainties σ_{ED} and σ_L (on $L_{*,Kp}$) in
 325 quadrature to $E_{Kp,\text{flare}}$.
 326

327 3.3. Power law fits

328 Flare frequency distributions follow power law relations that
 329 cover several orders of magnitude, from solar microflares to
 330 stellar superflares. We fitted power law functions to the FFDs using
 331 three different approaches.

332 The first method was a maximum likelihood estimator
 333 (MLE) (Maschberger & Kroupa 2009). As recommended
 334 by Maschberger & Kroupa (2009), we applied the stabilized
 335 Kolmogorov-Smirnov (KS) test at 95 % significance level to all
 336 power law fits in the sample. If the test fails the power law model
 337 does not fit the data at the given significance level. If the test
 338 passes, this does not give any information whether the power
 339 law model is the correct assumption. The goodness of fit can
 340 be estimated from the visual inspection of percentile-percentile
 341 plots, given in the online material⁴. We used the KS test itera-
 342 tively to determine the FFDs' low-energy cutoff ED_{\min} for the
 343 power law distribution. This cutoff does not reflect the physical
 344 threshold for criticality because the cutoff is seen at lower ener-
 345 gies in similar stars with higher sensitivity, for example, higher
 346 candence. The cutoff also does not directly imply that flare can-
 347 didates detected above or below the cutoff are more or less likely
 348 to be detected because the flare detection probability is a func-
 349 tion of both duration and amplitude, and not only of energy.
 350 Above all, it is not straightforward to account for the deviation
 351 from an ideal power law at low energies, because the aforemen-
 352 tioned effects may be partly cancelled by background contam-
 353 ination from, for instance, cosmic rays (?). We believe that we
 354 are mostly limited by the non-linear dependence for the energy
 355 bias from time sampling effects (?) and recovery probability on
 356 flare duration and amplitude. These parameters are not resolved
 357 in FFDs, and while they are correletad there is significant spread
 358 in the duration-amplitude relation to blur the cutoff in th e FFD.
 359 One way to account for this circumstance is to inject and recover
 360 synthetic flares with a variety of durations and amplitudes and to
 361 determine energy ratios and recovery probabilities for each in-
 362 dividual candidate, assuming that the underlying flare shape can
 363 be sufficiently well parametrized, as was done in Davenport et al.
 364 (2014)

365 The second method used the MLE result as a prior for α . Follow-
 366 ing Wheatland (2004), we defined the joint posterior distribution
 367 for the probability ϵ that a flare with ED or energy above some
 368 value S_2 occurs within a time period ΔT :

$$p(\epsilon, \alpha) = C \cdot (-\ln(1 - \epsilon))^M \cdot (\alpha - 1)^M \cdot \Gamma(\alpha) \left[\frac{(S_2/S_1)^{M+1}}{\pi} \right]^\alpha \cdot (1 - \epsilon)^{(T/\Delta T) \cdot (S_2/S_1)^{\alpha-1} - 1}. \quad (2)$$

369 C is the normalisation constant, M is the number of events,
 370 the total observation time. Γ contains the prior distribution for α .

and S_1 denotes the detection threshold above which all flares are
 detected. π encapsulates the flare energies as

$$\pi = \prod_{i=1}^M \frac{s_i}{S_1} \quad (3)$$

, where $\{s_1, s_2, \dots, s_m\}$ are the flare energies or ED .

The posterior distribution in Wheatland (2004) captures both the Poissonian distribution of flare events in time, and their power law distribution in energy, simultaneously. Wheatland (2004) derived this model to be able to predict the flaring rate of a given active region on the sun, and offered an extension to Eq. 2 that treated changing flaring activity rates as the active region evolves, and also characteristics of the active region itself, such as sunspot classifiers. In our simplification of the model, we assumed that the flare generating process did not change within the observation time span in any star in our sample ($M = M'$ in Eq. 24 in Wheatland (2004)). Another assumption was that this process was the same for all stars in the sample ($\Lambda_{MC} = 1$ in Eq. 24). Under these assumptions the information gained from the light curves could be stacked together.

With a uniform prior for α the results from the MLE and Markov Chain Monte Carlo (MCMC) sampling from the posterior distribution are the same, the latter allowed us to fit for ϵ and α simultaneously. Another advantage of the latter approach is that we could use more informative priors.

We chose our prior to reflect the power law exponent results discussed in the literature. The studies we took into account analysed flare frequency distributions of stellar flares in the optical regime, and focused mostly on K and M dwarfs (Lurie et al. 2015; Howard et al. 2019a; ?; ?) or ultra-cool dwarfs (?) but also solar-type stars (Shibayama et al. 2013). We also used a Gaussian fit to α obtained from the posterior distribution using the full sample of flares as the prior for a subsequent Bayesian analysis of individual age and T_{eff} bins. Assuming that α is universal for all spectral types, ages, and flare energy ranges, we used this more informative, Gaussian prior to further constrain the flaring rates.

Additionally we calculated the exceedance statistic tr to test if the power law distribution was truncated. If tr is 1, the power law distribution is truncated at the high energy end. If tr is 0, no information was gained from the calculation. To derive tr , given a number n of observations X_n and a best fit value for the power law exponent, we generated 500 samples with n values from this best-fit distribution assuming no truncation, i.e. choosing an upper limit several orders of magnitude higher than X_{max} . We then proceeded to truncate the samples at thresholds T below the maximum observed value X_{max} and determined the average number N_{ex} of generated values that will exceed T . If the underlying power law is not truncated, N_{ex} declines with larger n , as larger X_{max} will be present in the original data. If the best fit power law exponent is steeper, N_{ex} will be underestimated. If the best fit power law exponent is flatter, N_{ex} will be overestimated. If the power law is not truncated, for $n \geq 100$ N_{ex}/n will be $< 5\%$, for $20 < n < 100$, typically $N_{ex}/n < 15\%$.

4. Results

Fig. ?? shows the $E_{Kp,\text{flare}}$ and ED detection thresholds, as defined by the recovery probability (see Sec. ??). The thresholds in ED reflect the noise level in the light curves.

428	4.1. Flaring activity as a function of age and T_{eff}	473
429	Flaring activity decays with age. Flaring fraction was observed	474
430	to decline with galactic latitude for M dwarfs (Hilton et al.	475
431	2010)Howard+2019. Short rotation periods and high magnetic	476
432	activity measured in H α are strongly correlated (West et al.	477
433	2015). According to gyrochronology, fast rotation indicates	478
434	young age (Barnes 2003), and slows down as the star ages. Here	479
435	we quantify how this decline unfolds for different spectral types	480
436	Except for the stars in our coolest temperature bin (M5.5-M8	481
437	2 500-3 000 K), stellar flaring activity at a given age is always	482
438	stronger for a cooler star. The exception is seen at cluster ages	483
439	around 120 Myr.	484
440	What creates the strong emission in white light? Extended flare	485
441	loops, maybe (?)	486
442	4.2. M67	487
443	We found one very likely flare candidate in the PSF-detrended	488
444	light curves (Nardiello et al. 2016). After having searched the	489
445	entire sample we identified about 250 candidates. We excluded	490
446	those candidates that clustered spatio-temporally in different	491
447	light curves as systematics. After vetting the remaining 25 by	492
448	eye, we excluded false positives judging by their morphology,	493
449	leaving a mere ten light curves with flare-like shape. One target	494
450	get appeared to be an echo from one of the other light curves.	495
451	Five targets were foreground stars, two are more likely background	496
452	stars, one target is probably a giant and does not appear in Gaia photometry (IR source). Only one target (Gaia DR2	497
453	604922435422864512) appears to reside at M67 distance and is	498
454	a $p = 0.997$ member according to Gao (2018). Our estimates	499
455	indicate that it is a M2V. If the spectral class is correct, the flare	500
456	releases about $6.1 \cdot 10^{33}$ erg ($ED = 1391 \pm 548$ s) in the Kepler	501
457	band.	502
458		503
459	4.3. Flaring Activity Indicators	504
460	Flaring rates: FR and flaring fraction We define FR as the flaring	505
461	rate above detection thresholds on $E_{\text{Kp,flare}}$ and ED in each	506
462	bin, respectively (Figs. ?? and ??).	507
463	Flaring energy: FA and $L_{\text{Kp,flare}}$ The energy released in flares	508
464	was inferred using our derived stellar luminosities. It declines	509
465	with age for every T_{eff} bin considered for both the total luminosity	510
466	and relative to the quiescent flux (Fig. ??).	511
467	$L_{\text{Kp,flare}}$ is the luminosity in flares in the Kepler band. We can relate this to the quiescent bolometric luminosity of the star when we define the fractional flare luminosity FA as in Paper I:	512
468	$FA = \frac{1}{N} \sum_i^N FA_i = \frac{1}{N} \sum_i^N \frac{E_{\text{Kp,flare,tot},i}}{t_i \cdot L_{\text{bol},*,i}}$	513
469	We determine $L_{\text{bol},*}$ from R_* and T_{eff} , as described in Sec. 2.2. This is a meaningful measure of relative stellar activity as long as only the flux portion of the quiescent star in the Kepler band is roughly constant. It is therefore sensible to compare FA values across ages, but not across T_{eff} .	514
470		515
471	FFD Power law fit parameters to the FFDs (Figs. 5 and 6)	516
472	sensitive to the low-energy cutoff, where most observations side. The goodness of fit strongly depends on the sample size	517
473	Power law fit parameters derived using MLEs, as described in Sec. 3.3, are mostly consistent with each other but often deviate	518

from $\alpha = 2$. A smaller sample size tends to create a flatter distribution (Figs. 7 and 8). Truncation was not detected for FFDs with more than 50 flares (Tables 2 and 3) For these results, extrapolations outside of the observed energy range are clearly off. If we assume $\alpha \equiv 2$, different distributions can be compared. For fixed α , in the ED domain, β_2 is the flare frequency at $ED = 1$ s, and shows a trend in both T_{eff} , and age (see Fig. ??). In the energy domain, the picture is less clear (Fig. ??).

Compare to other FFD values, e.g., from Ward's Evryscope survey, see table in Appendix, and maybe convert it to a plot Howard et al (2019) monitored superflares on cool stars with bolometric energies above 10^{33} erg and up to 10^{36} erg. They find power law exponent values around ~ 2 resolved by spectral types. Similar values are found for individual flare stars (Lurie et al. 2015).

Howard+18, Loyd+18, Tilley+19 show that flares can erode exoplanetary atmospheres. If a flare is assumed to deposit its UV energy in an instant a single superflare can completely remove the ozone layer at the substellar point Loyd+18. Associated protons are safer way to ozone destruction if they are associated with reoccurring large flares Tilley+19

5. Discussion

5.1. Consistency with other studies

EvryFlare, mass-dependence,

5.2. Flaring and rotation

More energetic flares can be expected from faster rotating stars (Candelaresi et al. 2014; Doorsselaere et al. 2017; Yang et al. 2017). Findings that flares with intermediate Rossby number appear to flare more than fast and slow rotators (Mondrik et al. 2019) could not be reproduced here or in the EvryFlare survey (Howard et al. 2019b). If enhanced flaring can be interpreted as an increase in the stellar angular momentum loss rate flaring activity can be used to inform the cause of variation in the spin-down efficiency. An example of such variations is the apparent temporary stalling of spin-down seen in K dwarfs in NGC 6811 (Curtis+2019). The authors favored a scenario in which the stellar core transfers momentum onto the envelope but did not rule out the possibility of a decreased magnetic braking efficiency. In the latter scenario, these stars should flare less.

We used rotation periods derived from K2 light curves for the Pleiades (Rebull et al. 2016b), the Hyades (Douglas et al. 2016), and Praesepe (Rebull et al. 2017), to illuminate the rotation-flaring relation at fixed ages. In the Pleiades, most flaring stars are found on the fast rotator branch at or below one day, and flaring activity peaks in this regime. For Praesepe, flaring rates appear to ...[...]. In the Hyades, all of the 11 stars with rotation periods that overlapped with our sample were found flaring, but the number were too low to provide statistical insight. For Rup 147, M35 and M67, no rotation rates were available at the time.

5.3. M37

Comparing our results to a similar study of photometric flares in M37 (Chang et al. 2015) we find the results somewhat discrepant. M37 is 300-600 Myr old and appears less active than Praesepe and Hyades in individual Teff bins, which are of coeval or older. We attribute the difference to the loose membership requirement of $pmem \geq 0.2$ in Chang et al. (2015) as compared to our stricter cuts at 0.8. We expect the M37 to be contaminated

Table 2. Summary of activity parameters of all clusters and T_{eff} bins in energy distributions.

529 with field stars that systematically reduce the flaring rates. 530 applying our own restriction the M37 sample (Chang et al. 2016) 531 leaves very few flares that hamper a statistical description of the 532 distributions. 533

5.4. Division at 3000 K

534 The lowest T_{eff} bin at Pleiades age in our sample reflects the 535 division between fully convective stars and those with a radiative 536 core (Reid & Hawley 2005). At this age, the coolest dwarfs 537 may still be accreting angular momentum on the PMS, instead 538 of spinning down on the MS. We suggest that a regime change 539 occurs around 120 Myr for stars with $T_{\text{eff}} = 2500 - 3250$ K. 540 Below 3000 K, an analysis of 66 ZDI maps show that magnetic 541 field configurations can be strong and dipolar or weak and 542 tipolar (Morin et al. 2008; See et al. 2017). If these stars can be 543 distinguished by age, this should be reflected in our age-resolved 544 flaring activity. If the difference is not a function of age, 545 should see a similar bimodal distribution of very inactive and 546 very active stars in the lowest mass bins. If the difference 547 between the two configurations is a function of age, we should only 548 see one type of stars with correspondingly similar behaviour 549 in these T_{eff} bins. 550

The lowest mass bin appears underactive compared to the rest of 551 the flaring-age- T_{eff} relation in the ED domain. Physical explanations 552 for this peculiarity include: A different magnetic structure 553 A truncation of the power law that reflects the maximum ED_{max} 554 active region can produce on these stars. 555

West et al. (2015) found that all M1-M4 dwarfs with rotation 556 periods shorter than 26 days, and all M5-M8 dwarfs with periods 557 shorter than 86 days show H α emission, indicating their mag- 558 netic activity. 559

Assuming a typical binary fraction for early and mid M2 560 dwarfs (Fischer & Marcy 1992), we can expect some of the flares 561 on stars at $T_{\text{eff}} > 3000$ K to belong to unresolved binary com- 562 panions with $T_{\text{eff}} < 3000$ K. A misattributed flare on an early M1 563 dwarf then will be assigned a too small ED , but still a corre- 564 $E_{Kp,\text{flare}}$ because the count ratios are equal to the L_{Kp} ratios. 565

5.5. Consistency of Hyades' and Praesepe's results

HRDs constructed in Gaia Collaboration et al. (2018a) indicate 566 only slightly older ages for Hyades and Praesepe. We expect our 567 results to reflect this similarity. 568

Are the samples comparable? Membership determination may 569 differ. Can we frame this as a statistical test, i.e. answer the 570 question: What is the probability that the activity distributions 571 for both clusters were drawn from the same underlying distribu- 572 tion for a given age and mass bin? 573

Metallicity is controlled for ([Fe/H](Praesepe) = 0.66, 574 [Fe/H](Hyades) = 0.13, Netopil et al. 2016). 575

5.6. Consistency of Pleiades and M35 results

M35 is has subsolar metallicity, while Pleiades are roughly solar. 576

5.7. Jim's section(s)

Flaring activity function of mass and age – a gyrochronology 579 analog? 580

Results in the context of Davenport et al. (2019): How well does 581 the model fit if we have isochronal and not rotational ages 582 for our stars? 583

Davenport et al. (2019) note a sample bias towards more active stars. Their models overpredicts the superflaring rate of the average Sun-like sample from Shibayama et al. (2013) and more resembles the rate for their most active sub-sample. Do we see the same effect in our OC sample? We should not. Or cluster memberships depend on activity. 587
588
589

5.8. Universality of α

Taking into account uncertainties and systematic errors resulting power law fitting methods, the power law exponent $\alpha \sim 2$ appears to be the same for all studies on flare statistics so far, irrespective of spectral type. A notable exception are A stars in Kepler that follow a power law with $\alpha \sim 1$ that may indicate a different physical process (Yang & Liu 2019).

5.9. Deviations from single power law

Spots can survive on the stellar surface from a few days to nearly a year (Namekata et al. 2017; Davenport 2015). Namekata et al. (2017) find conceivable that spots evolve on timescale shorter than the estimated lifetimes. Complex spot geometry is correlated with the strongest X-class flares on the Sun (Toriumi et al. 2017; Sammis et al. 2000). This supports the idea that flares are associated with the presence of certain types of starspots, or more generally, certain types of active regions. Since we can reasonably expect that there is a maximum flare energy a spot can produce, the underlying power law relation must break a some ED_{max} . We tested a possible truncation of our FFDs, but find no conclusive evidence for it in any FFD with > 50 data points. As we stack multiple targets, each potentially with multiple, evolving spots of various sizes on their surfaces, into one FFD at a time, we might observe a deviation but no truncation. A different explanation is simply that we do not sample the maximum energies, as extremely high relative fluxes have been observed in the past (Paudel et al. 2018; Jackman et al. 2019; Schmidt et al. 2016).

6. Summary and Conclusions

Is there or will be there more data available to further extend the sample? There are no model-independent stellar ages. It is more correct to speak of evolutionary stage. Stars in open clusters with precise isochronal ages have their observables reduced to a number of years. We can now ask: Can we unambiguously map flaring evolutionary stage to the evolutionary stage of isochronal fit parameters of a given star? If there is either a strong correlation, or even a physical relation between flaring activity and, for instance, mass and rotation rate, the answer is yes. If this relation is sufficiently sensitive to be captured by present day instrumentation, and non-degenerate in the relevant parameters, flaring activity can be integrated into the family of age indicators, and complement and extend them.

Ultimately, flaring activity depends on how efficiently the star converts its energy budget to flares throughout its lifetime. Since the fraction of total luminosity released in flares is small even for the most active stars, this efficiency need not scale with the overall energy budget of the star on the MS, but will more likely depend on the ability of the star to use this budget to produce magnetic surface topologies and strengths that enable flaring.

A magnetic dynamo, driven by rotation and convection, introduces magnetic field to the system, that causes stellar wind that in turn removes angular momentum from star, decreasing its

rotation rate. Over time, the wind takes away more and more angular momentum, and the global magnetic field weakens! This is reflected in observations of chromospheric indicators (ZDI???). The decline is famously known as the Skumanich law, and gave rise to the rotational age-dating technique called gyrochronology. However, recent studies noted deviations from this rule, a stalling of the spin-down, and offered multiple competing explanations. It is not clear how these effects reflect on the small scale surface magnetic field. Chromospheric activity on solar type stars seems to continue to decline regardless of these rotational effects.

What about X-ray?

Observationally, not much can be directly said about the small scale topology of stellar magnetic fields beyond extrapolations from the solar case. On the Sun, chromospheric activity indicates line emission in excess of radiative equilibrium that is caused by magnetic fields. Likewise, magnetic field effects heat the corona

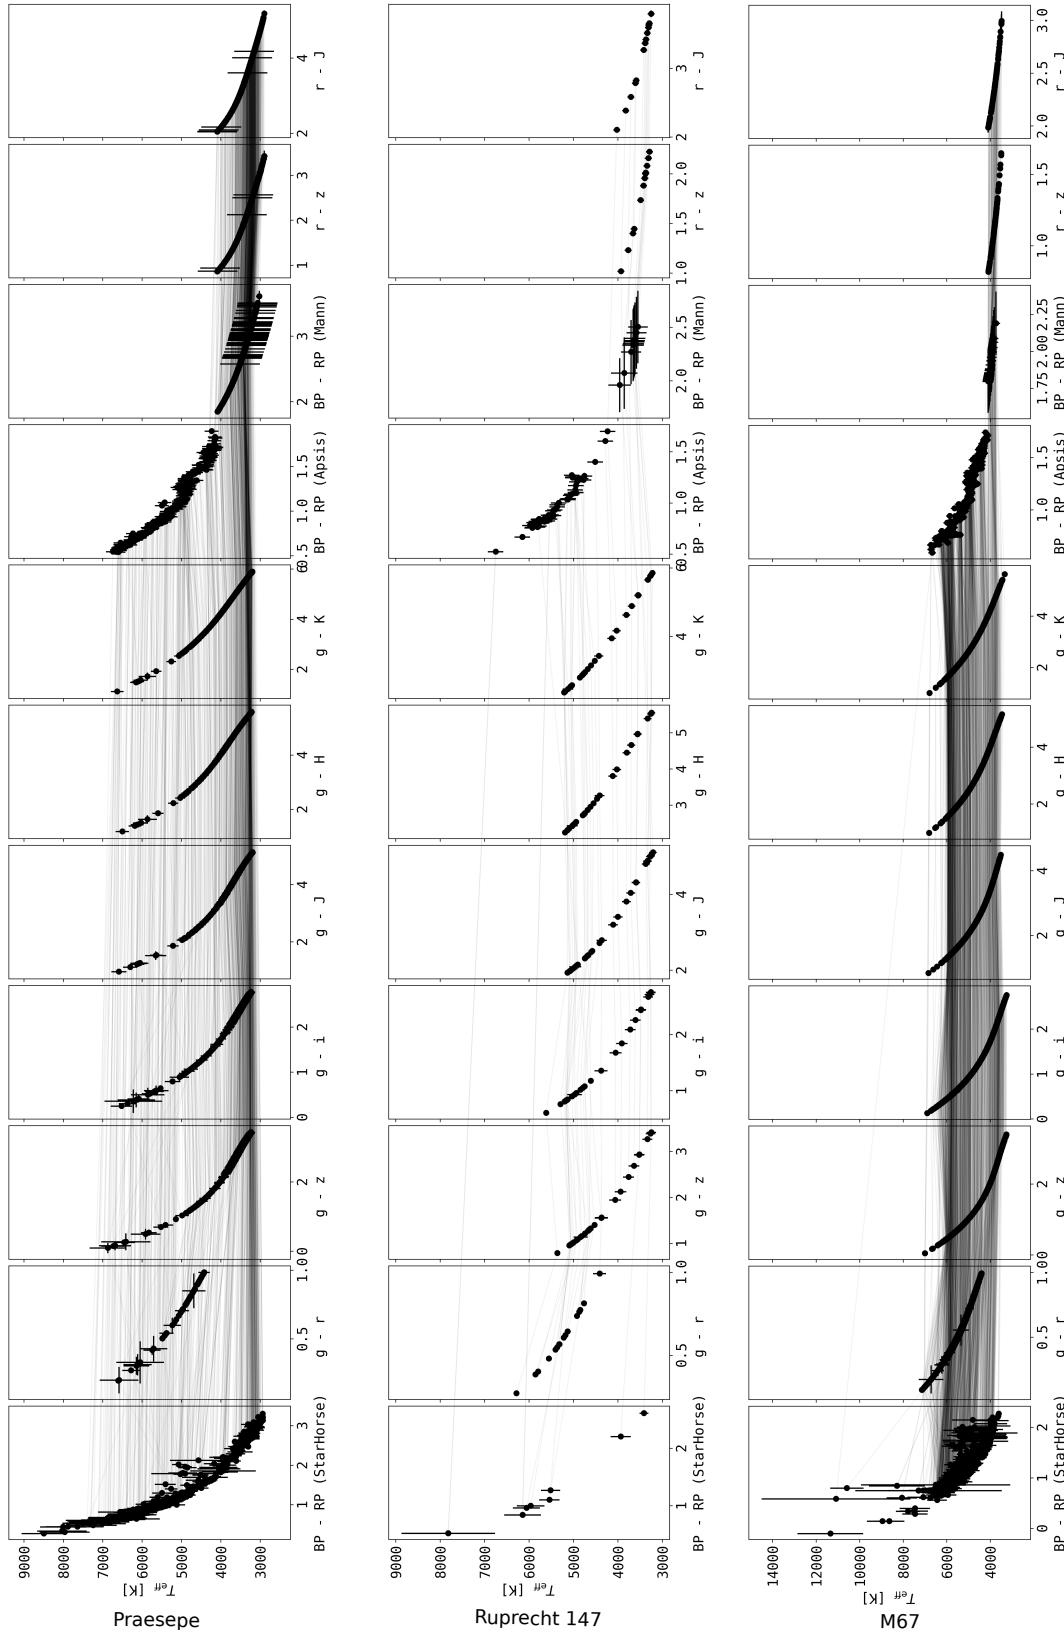

Fig. 3. Color-temperature relations for Praesepe, Ruprecht 147, and M67. Description as in Fig. 2.

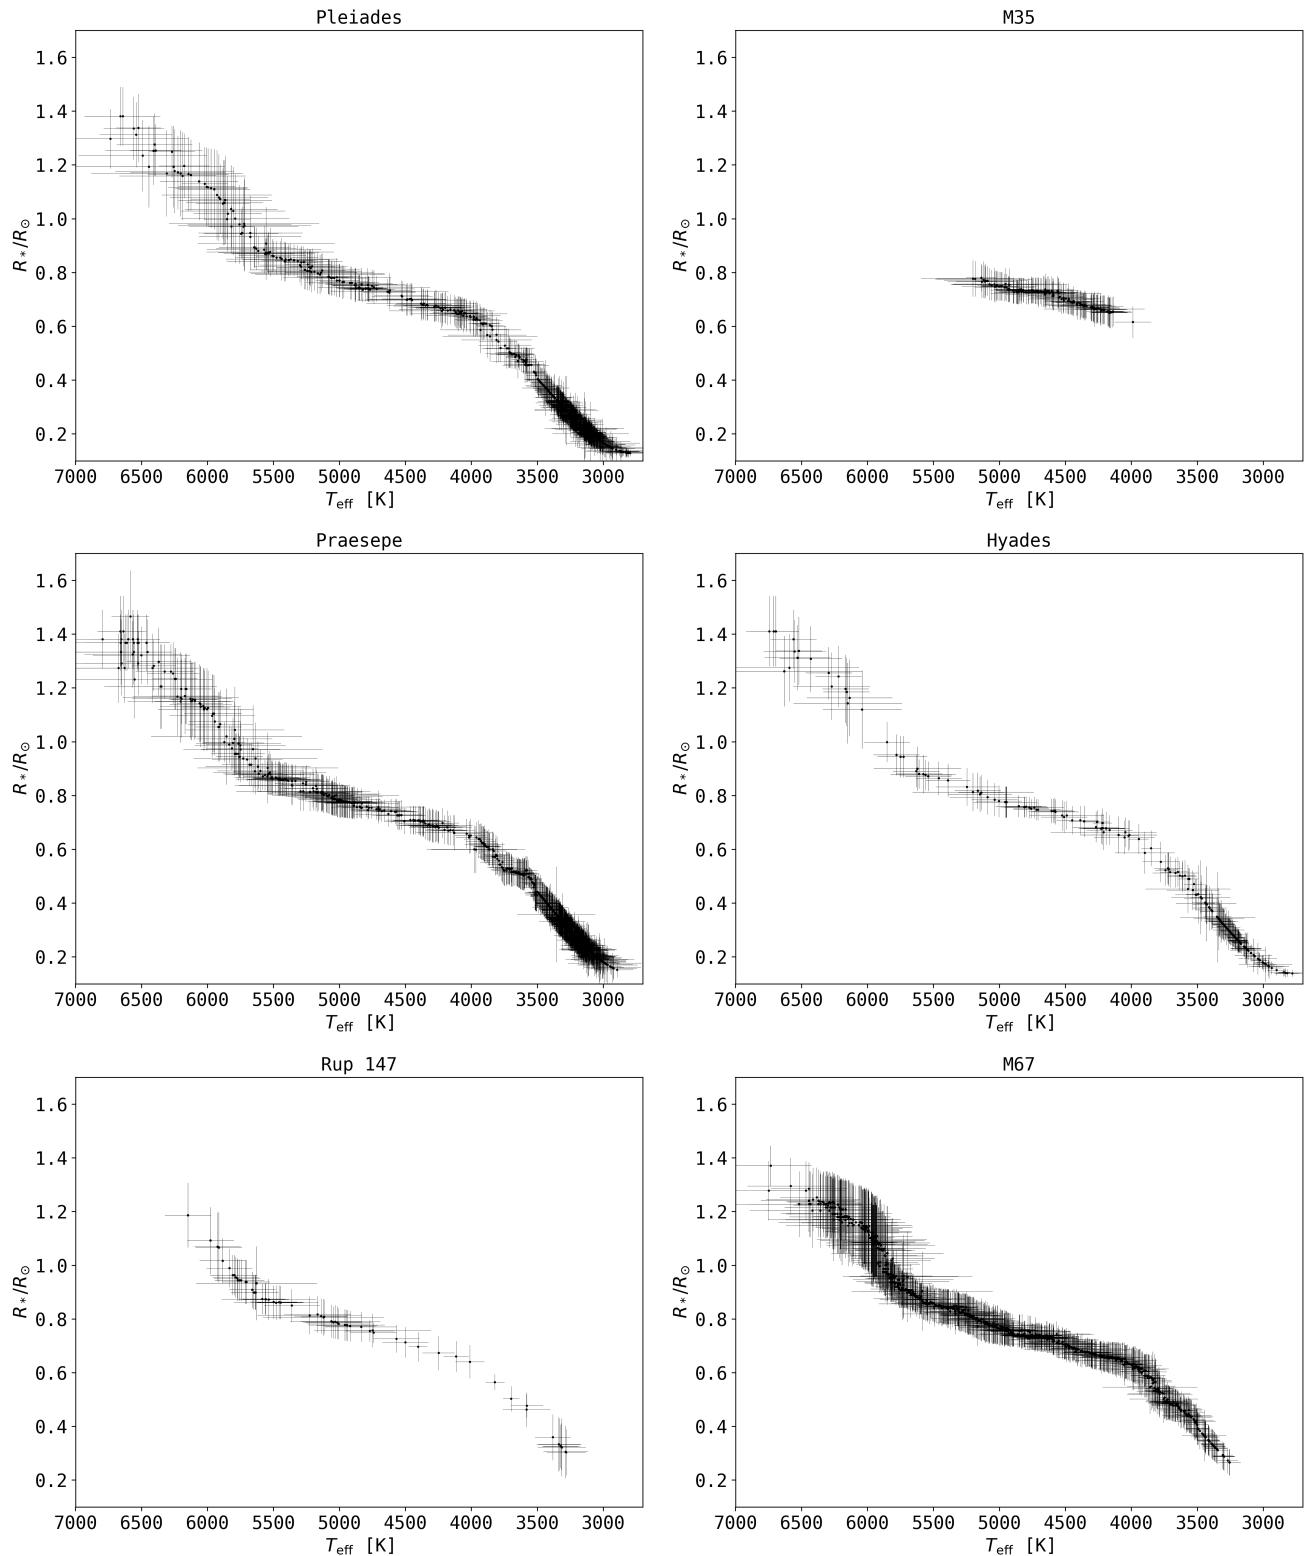

Fig. 4. $T_{\text{eff}} - R_*$ relation for all clusters in this study.

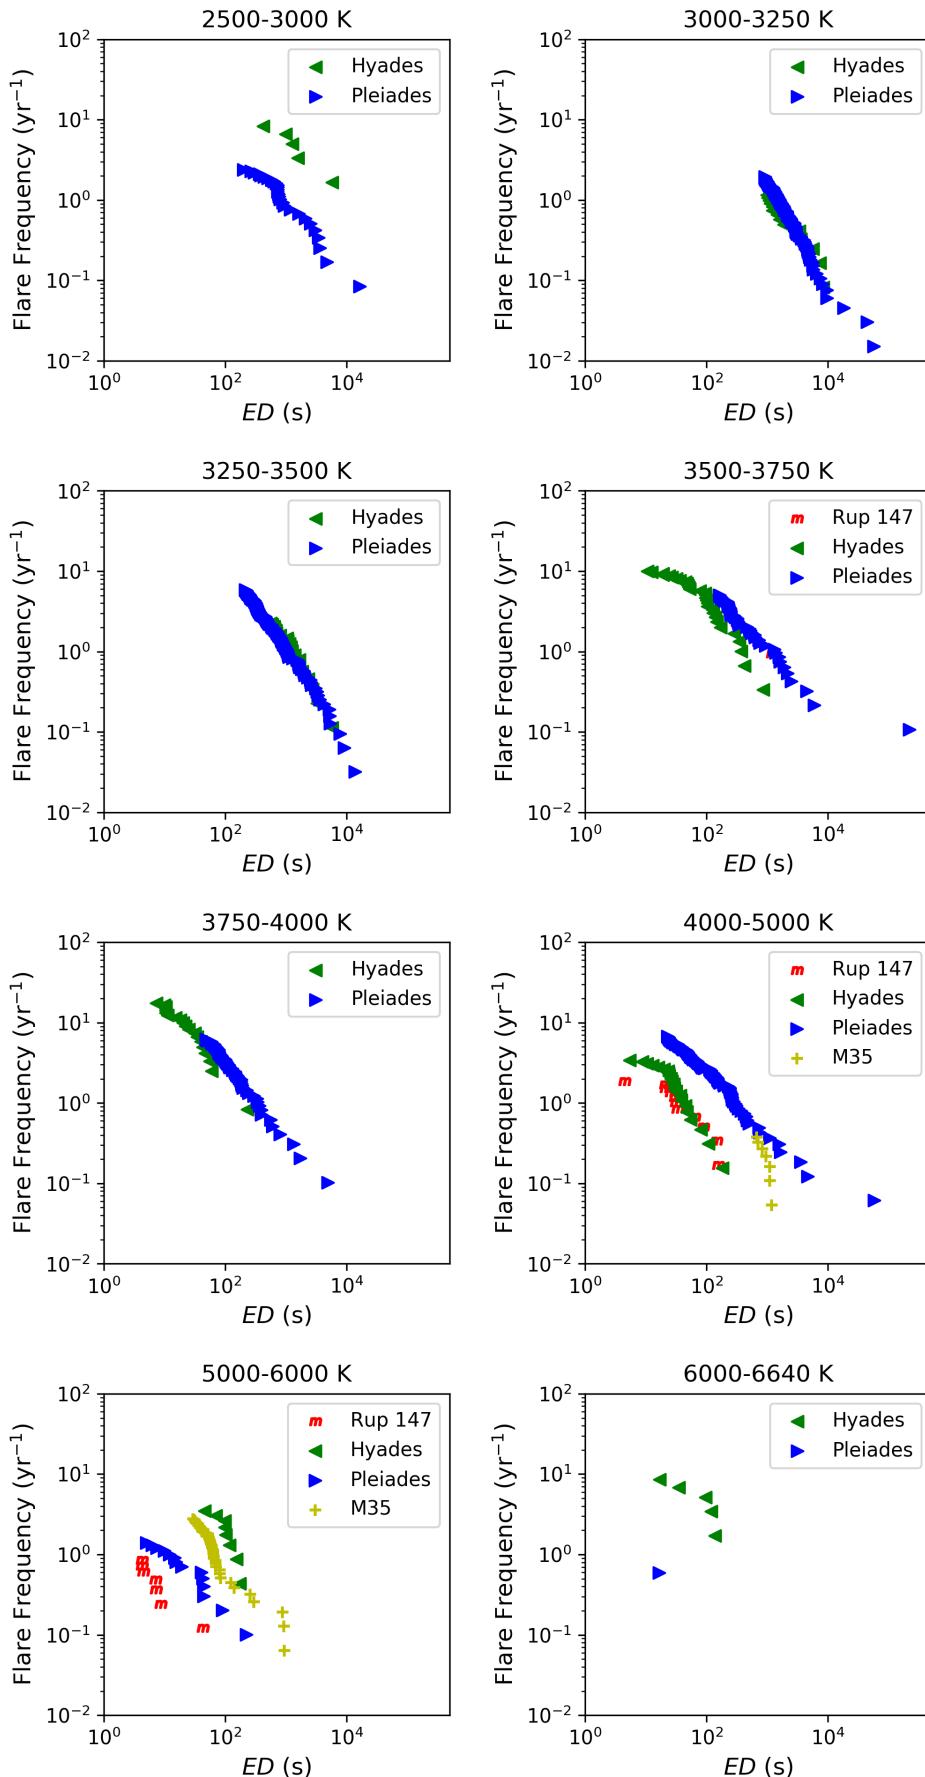

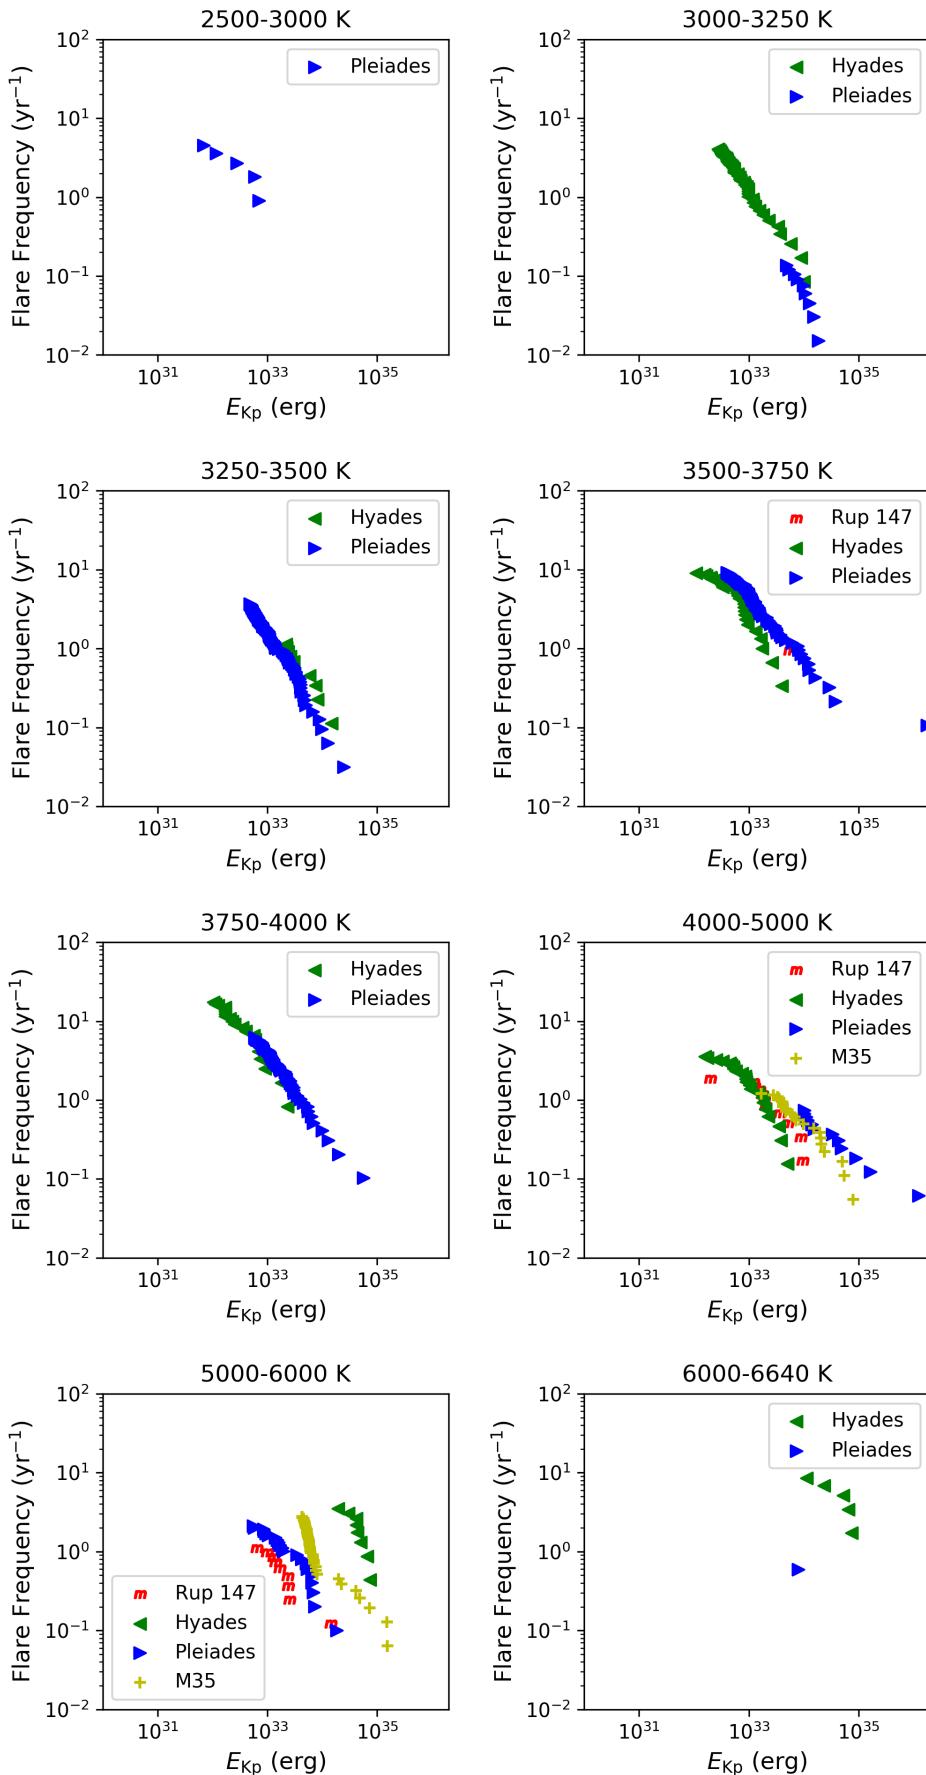

Fig. 5. Cumulative flare frequency distributions (FFDs) of equivalent durations (ED). In each panel, every distribution belongs to one cluster. The panels are binned by T_{eff} .

**Fig. 6.** Same as Fig. 5, but of Kepler flare energies $E_{\text{Kp,flare}}$.

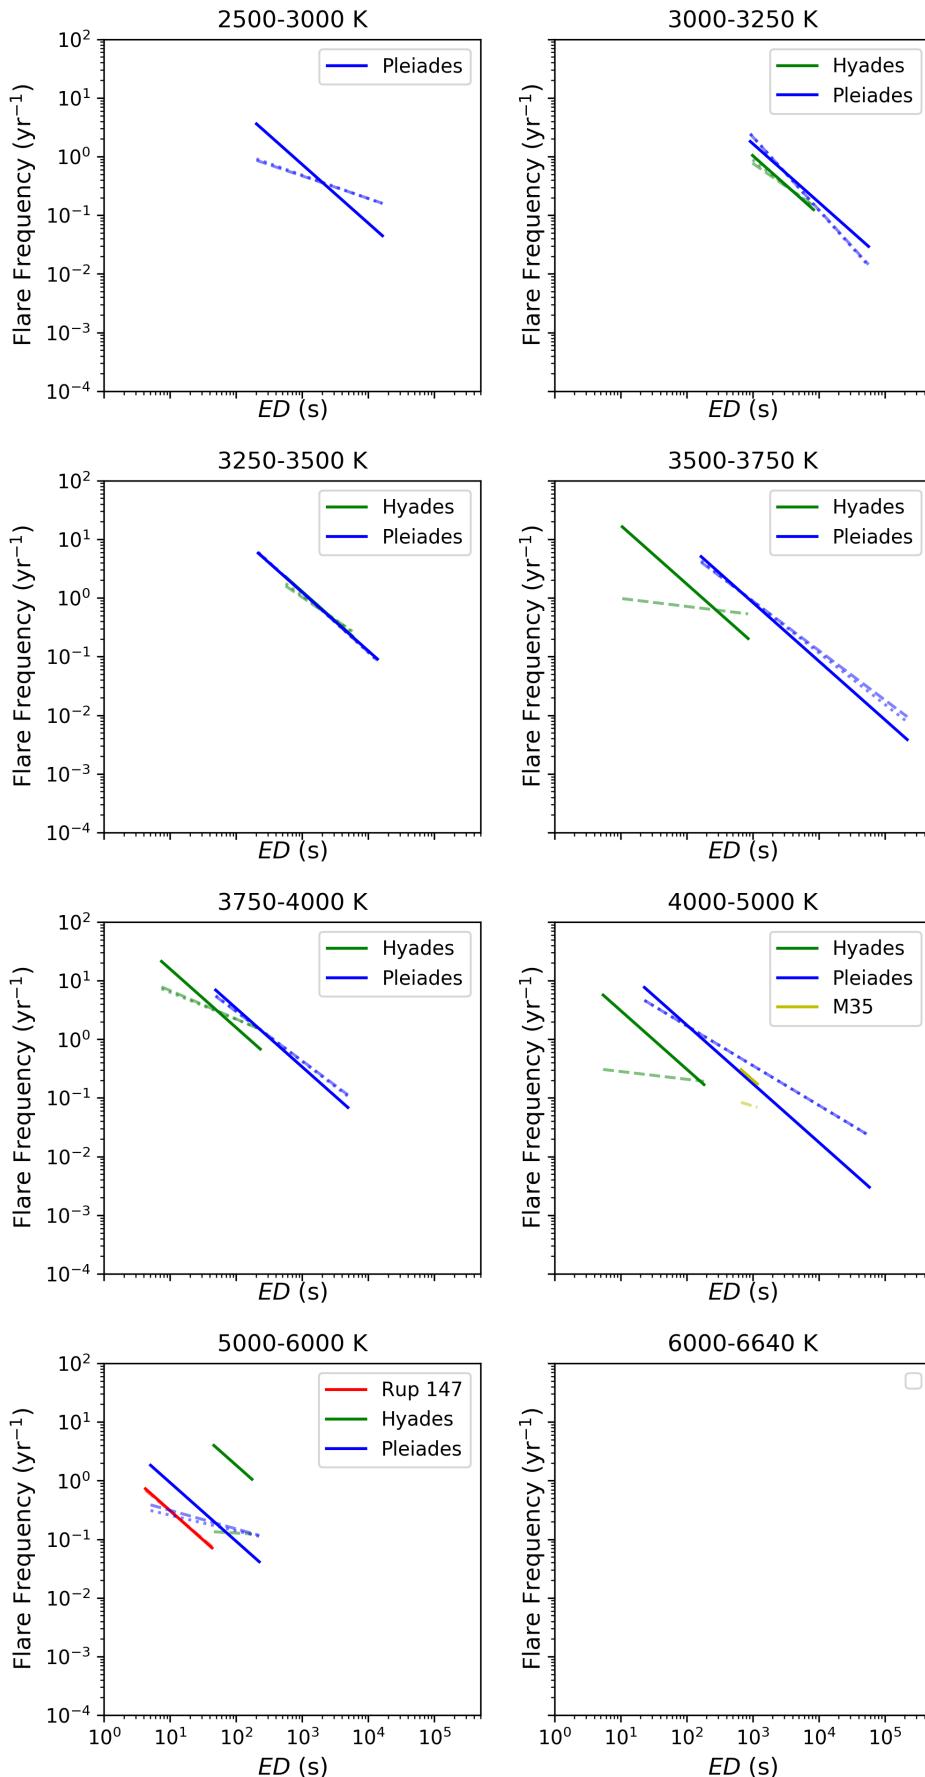

Fig. 7. Power law fits to the FFDs of ED in Fig. 5. Bold line: a power law with $\alpha = 2$. Dashed line: best fit parameters were determined following Maschberger & Kroupa (2009) (see Sec. XX). Dotted line: best fit parameters were determined following Bauke (2007) (see Sec. XX)

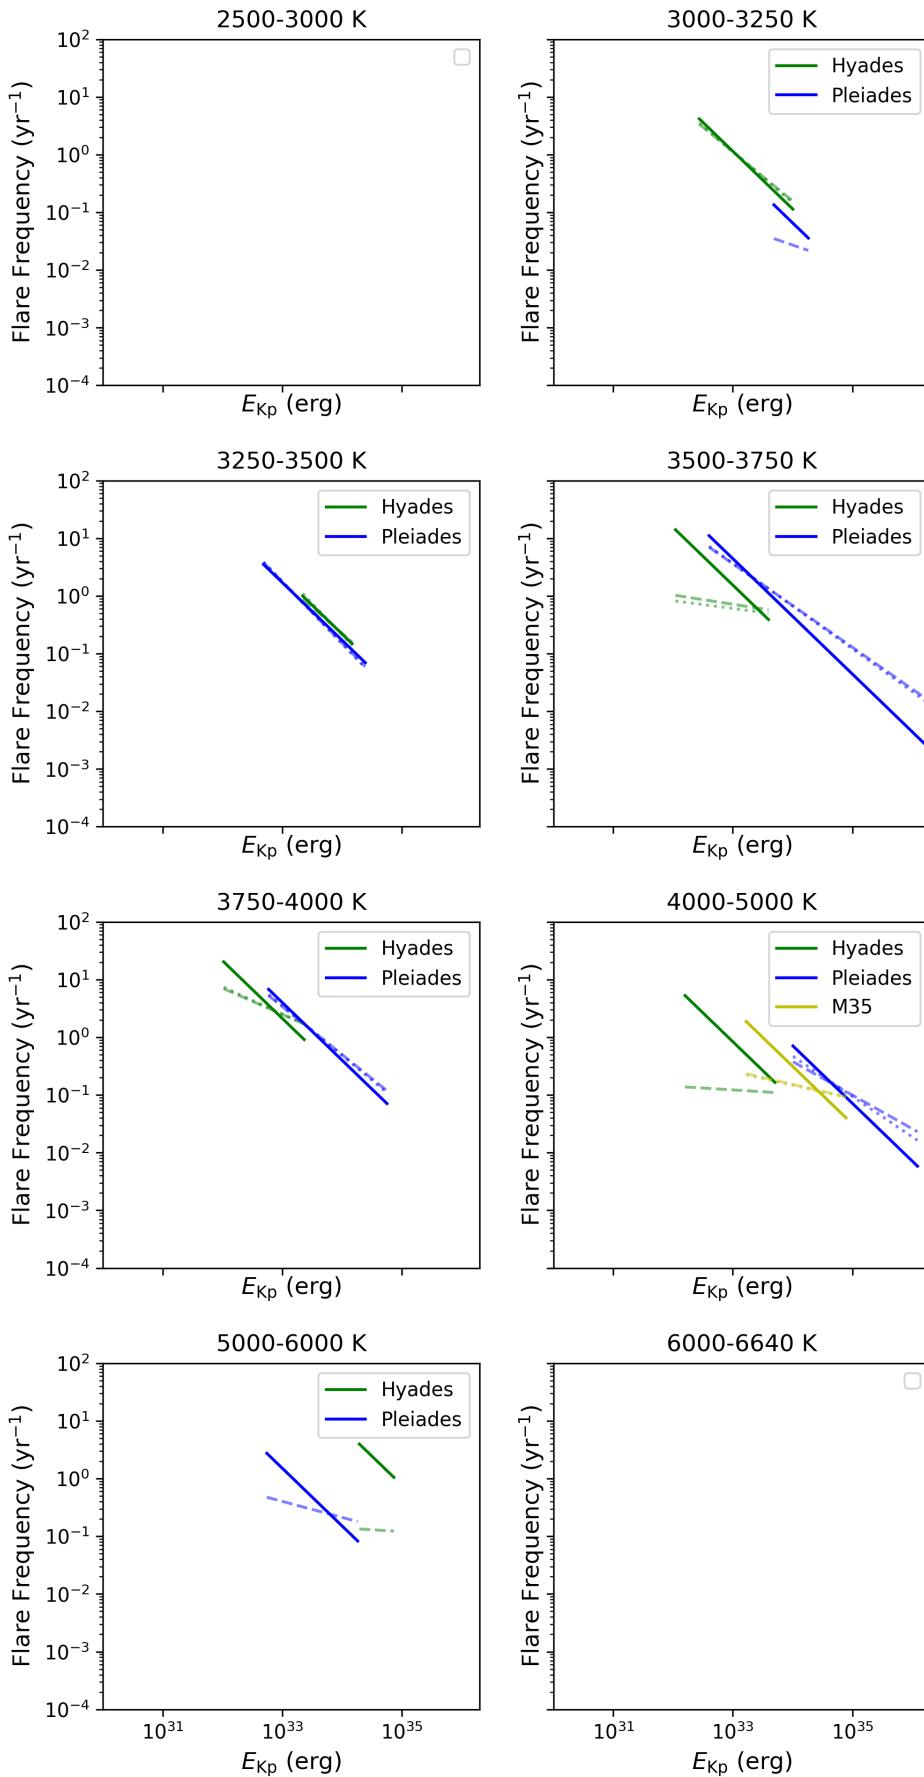

Fig. 8. Power law fits to the FFDs of $E_{\text{Kp,flare}}$ in Fig. 5. See Fig. 7 for details.

831 **Appendix A: Membership probabilities**861 **Appendix E: Solar system objects**

832 To match catalogs on RA and declination we used `astroML.crossmatch` tool for Python (Vanderplas et al. 2019)

833 For the studies with classifiers we assigned membership proba-

834 bilities as follows. In Gonzalez (2016):

$$\begin{aligned} p(M(\text{member})) &= 0.9, \\ p(BM(\text{binary member})) &= 0.9, \\ p(N(\text{non-member})) &= 0.1, \\ p(SN(\text{single non-member})) &= 0.1, \\ p(BN(\text{binary non-member})) &= 0.1, \\ p(U(\text{unknown member})) &= 0.5. \end{aligned}$$

836 In Curtis et al. (2013):

$$\begin{aligned} p(Y(\text{highest confidence member})) &= 0.9, \\ p(P(\text{possible/probable member})) &= 0.7, \\ p(N(\text{not likely/non-member})) &= 0.7, \\ p(B(\text{photometry consistent with blue stragglers})) &= 0.0. \end{aligned}$$

837 In Rebull et al. (2017):

$$\begin{aligned} p((\text{best})) &= 0.9, \\ p((\text{ok})) &= 0.6, \\ p((\text{else})) &= 0.1. \end{aligned}$$

838 Members from Rebull et al. (2016a); Douglas et al. (2017); and
 839 Gaia Collaboration et al. (2018a) were assigned $p = 0.9$ if they
 840 appeared in the final catalog.
 841 Table ?? gives an overview over different membership catalogues.
 842 Figure ?? shows membership probability histograms of the final
 843 sample broken down by membership source. Detailed instructions
 844 on how to reproduce the final sample of members in each cluster,
 845 and corresponding tables, Python scripts, and Jupyter notebooks
 846 can be found online⁵

847 **Appendix B: Cluster parameters**

887 As we have additional information in the form of uncertainties
 888 in our data $S = \{S_i, \lambda_i, \sigma_{S,i}\}$, we can expand Eq. ?? with this
 889 knowledge. Assuming that the observed flare energies S_i with
 890 cumulative rates λ_i are distributed around the real flare energies
 891 $S_{0,i}$ with Gaussian uncertainties $\sigma_{S,i}$, we can define:

$$\begin{aligned} p(S_i|\lambda_1, \alpha, \sigma_{S,i}) &= \frac{1}{2\pi\sqrt{\sigma_{S,i}}} e^{-\frac{(S_i - S_{0,i})^2}{2\sigma_{S,i}^2}} \\ &\quad - \frac{\left(S_i - S_1 \left(\frac{\lambda_i}{\lambda_1}\right)^{-1/(\alpha-1)}\right)^2}{2\sigma_{S,i}^2} \end{aligned} \quad (\text{G.3})$$

857 **Appendix D: Pixel saturation**

858 Resolve different levels of pixel saturation (>1 , >10) and how
 859 they contribute to the deviations from the single power law at
 860 the highest energies.

⁵ <https://github.com/ekaterinailin/flares-in-clusters-with-k2-ii>

861 Solar system objects (SSOs) produce brightness excursions in
 862 K2 light curves that can closely resemble flare signatures. Often,
 863 they can be distinguished by their symmetric rise and decay
 864 shape as contrasted with the typical fast-rise gradual decay flare
 865 shape (Davenport et al. 2014). M. H. Christiansen and colleagues
 866 developed a routine called SkyBoT that matches positions and
 867 times to passages of SSOs listed in YYY. RA, declination, start,
 868 stop, and mid epochs of flares in BKJD are the input parameters.
 869 We excluded all flare candidates that occurred within X minutes
 870 of a SSO passage at the star's position. This procedure removed
 871 ZZ% of all flare candidates. In the case of high energy flares, we
 872 confirmed the passage by manually inspecting the pixel file with
 873 the `lightkurve interact` function for TargetPixelFiles.

875 **Appendix F: Universality of power law exponent α**

876 We compiled a exhaustive (?) table of previous work where
 877 power laws were fitted to FFDs using different methods. Table
 878 ?? lists the overview. While particular studies consistently find
 879 values above or below $\alpha \approx 2$, the comparison of different studies
 880 points towards unresolved systematic errors in all these studies.

881 **Appendix G: Expanding the likelihood**

The rate λ_2 of flares with energies larger than S_2 is given in Wheatland (2004) as

$$\lambda_2 = \lambda_1 \cdot \left(\frac{S_1}{S_2}\right)^{\alpha-1}. \quad (\text{G.1})$$

S_1 denotes the energy above which all flares are detected. λ_1 is the corresponding rate. α remains the power law exponent of the flare frequency distribution.

We are also given the posterior distribution for the rate λ_2 of flares above S_2 in Eq. (20) in Wheatland (2004):

$$\begin{aligned} P_2(\lambda_2) &= \int_1^\infty d\alpha \int_0^\infty d\lambda_1 \delta\left(\lambda_2 - \lambda_1 \cdot \left(\frac{S_1}{S_2}\right)^{\alpha-1}\right) \\ &\quad \cdot P_1(\lambda_1) \cdot P_\alpha(\alpha) \end{aligned} \quad (\text{G.2})$$

As we have additional information in the form of uncertainties in our data $S = \{S_i, \lambda_i, \sigma_{S,i}\}$, we can expand Eq. ?? with this knowledge. Assuming that the observed flare energies S_i with cumulative rates λ_i are distributed around the real flare energies $S_{0,i}$ with Gaussian uncertainties $\sigma_{S,i}$, we can define:

$$\begin{aligned} p(S_i|\lambda_1, \alpha, \sigma_{S,i}) &= \frac{1}{2\pi\sqrt{\sigma_{S,i}}} e^{-\frac{(S_i - S_{0,i})^2}{2\sigma_{S,i}^2}} \\ &\quad - \frac{\left(S_i - S_1 \left(\frac{\lambda_i}{\lambda_1}\right)^{-1/(\alpha-1)}\right)^2}{2\sigma_{S,i}^2} \end{aligned} \quad (\text{G.3})$$

We assume in Eq. ?? that uncertainties on λ_1 are negligible. Eq. ?? then reads:

$$\begin{aligned} P_2(\lambda_2) &= \int_1^\infty d\alpha \int_0^\infty d\lambda_1 \delta\left(\lambda_2 - \lambda_1 \cdot \left(\frac{S_1}{S_2}\right)^{\alpha-1}\right) \\ &\quad \cdot P_1(\lambda_1) \cdot P_\alpha(\alpha) \cdot P_S(S|\lambda_1, \alpha, \sigma_S) \end{aligned} \quad (\text{G.4})$$

Table A.1. Membership catalogs overview. No distance are given for Hyades we adopted individual distances for all members.

Notes. DANCe: DANCe membership study project. (1) Positions for Hyades were propagated to epoch 2000 using Gaia proper motions.

with

$$P_S(S|\lambda_1, \alpha, \sigma_S) = C \prod_{i=1}^M p(S_i|\lambda_1, \alpha, \sigma_{S,i}). \quad (\text{G.5})$$

894 C absorbs the normalization, or evidence term.

895 Following Wheatland (2004), we marginalize over λ_1 using the
896 δ function in ?? to obtain

$$\begin{aligned} P_2(\lambda_2) &= \int_1^\infty d\alpha \cdot P_1\left(\lambda_2 \cdot \left(\frac{S_2}{S_1}\right)^{\alpha-1}\right) \cdot P_\alpha(\alpha) \\ &\cdot P_S\left(S|\lambda_2 \cdot \left(\frac{S_2}{S_1}\right)^{\alpha-1}, \alpha, \sigma_S\right) \end{aligned} \quad (\text{G.6})$$

897 Transforming P_S into a function of ϵ with $\lambda_1 = -\ln(1-\epsilon)/\Delta T$
898 yields:

$$\begin{aligned} P_S(S|\epsilon, \alpha, \sigma_S) &= C \prod_{i=1}^M p(S_i|\epsilon, \alpha, \sigma_{S,i}) \\ &= \frac{C}{\Delta T(1-\epsilon)} \\ &\cdot \prod_{i=1}^M \left[\frac{1}{2\pi\sqrt{\sigma_{S,i}}} e^{-\frac{\left(S_i - S_2 \left(\frac{-\ln(1-\epsilon)}{\Delta T\lambda_i}\right)^{1/(\alpha-1)}\right)^2}{2\sigma_{S,i}^2}} \right] \end{aligned} \quad (\text{G.7})$$

899 Finally, P_S enters the joint posterior distribution from Eq. 2, that
900 becomes

$$\begin{aligned} p(\epsilon, \alpha) &= C \cdot (-\ln(1-\epsilon)^M) \\ &\cdot (\alpha-1)^M \cdot \Gamma(\alpha) \left[\frac{(S_2/S_1)^{M+1}}{\pi} \right]^\alpha \\ &\cdot (1-\epsilon)^{(T/\Delta T) \cdot (S_2/S_1)^{\alpha-1}-1} \\ &\cdot P_S(S|\epsilon, \alpha, \sigma_S). \end{aligned} \quad (\text{G.8})$$

901

Notes. ^(a) Bossini et al. (2019) noted some caveats for their determination of ages of young clusters, for which they used Gaia DR2 photometry for isochrone fitting. ^(b) Curtis (2016) reanalysed HIRES spectra using an improved spectroscopic method as compared to Curtis et al. (2013). ^(c) We did not adopt a mean value for the Hyades distance because the cluster members are on average closer than 50 pc.
