ABSTRACT

Context. Flares can help us trace magnetic activity because are bright and high-contrast on low mass stars.

Aims. This study aims to quantify flaring activity on these stars as a function of mass and age.

Methods. We automatically detected flares in K2 time-domain photometry, using the open-source software K2SC to remove instrumental and astrophysical variability from K2 light curves. We used injection and recovery of synthetic flares to assess detection thresholds, time sampling and de-trending effects on the inferred flare energies. With additional data from the full K2 archive we added stars with a larger variety of ages and spectral types to the analysis of the previous study (Ilin et al. 2019). We compared previous results from the Pleiades and Prasepe to the flare frequency distributions (FFDs) in M35 and the Hyades, respectively. Ruprecht 147 filled in the age gap at 2.5 Gyr between the aforementioned young clusters and the solar age cluster M67.

Results. We find that the flare production mechanism is similar for the entire parameter space, following a power law relation with exponent $\alpha \approx 2$, but the flaring frequencies depend on both mass, and age. We discuss X and Y.

Key words. Methods: data analysis, Stars: activity, Stars: flare, Stars: low-mass

1. Introduction

Flares are explosions on stellar surfaces with a complex spatiotemporal and energetic phenomenology. We know that flares are magnetic re-connection events that lead to a change in field line topology and subsequent energy release (Priest & Forbes 2002). We can observe flares in nearly all electromagnetic bands, from radio to X-rays, and on all stars that possess a convection zon⁸⁷. from late F type stars to ultracool dwarfs (Gizis 2013). But even with continuous monitoring at high temporal resolution, the range dom occurrence of solar flares makes them costly observing targets, especially in coordinated multi-band observations. In integrated light, most solar flares have a far too low contrast and intensity to be observable. Stellar flares on cool stars have two advantages in this respect. They are often bright, enhancing stel-14 lar flux by up to several orders of magnitude, and they typically 15 than their stars' photospheres.

exhibit blackbody emission at temperatures significantly higher 16 17 With the evidence that the physical processes that cause flares 18 on the Sun and other stars are the same (Karoff 2016), so 19 lar and stellar flares can inform each other (Shibayama et as.) 20 2013). Inconsistencies in extrapolations from solar to stellar con 21 ditions (Aarnio et al. 2011; Aarnio et al. 2012; Drake et al. 2013) 22 provide valuable clues to the differences in magnetic properties 23 between Sun and M dwarfs, too (Alvarado-Gómez et al. 2018). 24 Large surveys like Kepler and TESS enable statistical flare stu 25 25 ies of stars that were not pre-selected for their activity (Walkow 26 icz et al. 2011). Statistical studies of stellar flaring activity can 27 help us understand the underlying physical processes CITE stel⁵⁸ 28 lar surface magnetic fields, starspots (Davenport 2015; Howard

et al. 2019b), how flares relate to stellar angular momentum evolution (Mondrik et al. 2019; Howard et al. 2019b), how they affect the atmospheres of exoplanets (Lecavelier des Etangs et al. 2012; Loyd et al. 2018; Tilley et al. 2019; Howard et al. 2019a), and inform galactic archaeology (Howard et al. 2019a).

Basic parameters that affect flaring behaviour on stars are their masses, and ages. Ages can be controlled for in coeval groups of stars, and flaring-age studies in binaries showed consistency in activity for both components in the majority of targets (Lurie et al. 2015; Clarke et al. 2018). Open clusters present other coeval groups of stars with well-determined ages. Ilin et al. (2019) (hereafter PaperI) investigated the flaring activity of late-K to mid-M dwarfs in three open clusters (OCs), the Pleiades, Praesepe, and M67, using K2 time domain photometry. They analysed the flare frequency distributions (FFDs), with respect to different masses and cluster ages. For the cluster members, the light curves revealed that their flaring activity declines both with age and mass. The decline is faster for higher mass stars. Recently, Davenport et al. (2019) put forward an empirical parametrization of this flaring-mass-age relation based on FFDs. The present study aims to extend the results in PaperI to the age of Ruprecht 147 (2.5 Gyr), and both higher and lower masses than in the previous study. We also test the previous results from the Pleiades on M35, and the results from Praesepe on the Hyades, as both OC pairs have approximately the same ages. Because the Kepler satellite retired in fall 2018, we can now use the complete K2 data set, and supplement all three OCs in PaperI with additional light curves. Additionaly, we use high quality K2 light curves available for M67 (Nardiello et al. 2016) and M35 (Soares-Furtado et al. 2017). We discuss our results with

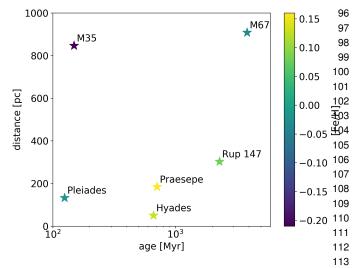

Fig. 1. The values for age, metallicity, and distance are approximated values from a compilation of existing literature, see Appendix B.1.

respect to potential breaks in the power law distribution at high energies. Finally, we use the results to test the parametrization in Davenport et al. (2019).

63 **2. Data** 119

Our main data are K2 target pixel files that were provided by the 64 Kepler archives hosted at MAST, and light curves derived from 65 66 them (Aigrain et al. 2016; Soares-Furtado et al. 2017; Vinícips 67 et al. 2018). To assign $T_{\rm eff}$ to the targeted stars we used multiband photometry obtained from Tycho, UCAC4, 2MASS, Par 23 68 STARRS, and Gaia catalogs. To assign ages to the targeted stars, 69 OC membership information was compiled from the literatul 25. 70 An overview over the cluster sample is presented in Table ?? al Al 71 127 72 illustrated in Figure 1.

2.1. K2 light curves

73

93

The Kepler (Koch et al. 2010) spacecraft finished its follow-µp 74 mission K2 (Howell et al. 2014) in September 2018, after having 75 completed nearly 20 80-day observing campaigns. Even thought 76 Kepler and K2 data are used in more than 2 400 publications 182 77 date, the public archive can still considered understudied (Bass 78 entsen et al. 2018). In this spirit we took up the analysis of about 79 4 000 Kepler target pixel files that each contain up 80 days of 835 80 min cadence observations in white light (4,200-9,000 Å). We 81 also used light curves extracted from the K2 C0 super stam9? 82 A super stamp is an aggregated set of typical Kepler postal@8 83 stamps placed over a densely populated field, that also covered 84 85 M35 (Soares-Furtado et al. 2017). As K2 was conducted on the two-wheeled Kepler satellite, it was 86 subjected to substantial drift motion (spacecraft roll, Van CleW2 87 et al. 2016) and had an overall reduced pointing accuracy. The 88 89 mitigate these effects, various solutions were developed (Vanderburg & Johnson 2014; Aigrain et al. 2016; ?; Luger et al. 44 90 91 2018) 92 145

2.2. Membership matching

We obtained membership information from multiple catalogsfor each cluster. We cross-matched these catalogs on RA and

declination within 3 arcsec. The resulting target lists were used to search the K2 archive, or were matched to the catalogs of extracted light curves from crowded fields in the case of M35 (Soares-Furtado et al. 2017) and M67 (Nardiello et al. 2016).

One part of the membership catalogs provided membership probabilities (Douglas et al. 2014; Bouy et al. 2015; Cantat-Gaudin et al. 2018; Olivares et al. 2018; Reino et al. 2018; Gao 2018; Olivares et al. 2019). For the other part no probability was provided (Rebull et al. 2016a; Douglas et al. 2017; Gaia Collaboration et al. 2018a), or qualitative classifiers were given (Curtis et al. 2013; Gonzalez 2016; Rebull et al. 2017). In the latter cases we assigned approximate probabilities anchored to the set threshold for inclusion into our final sample. Absence in a catalog did not decrease the likelihood of membership, as each catalog shows different selection biases which we did not address in this study. We set the threshold mean membership probability p for a target in our sample to 0.8.

2.3. Open Clusters

We studied flaring activity in the low mass stars in six open clusters spanning from ZAMS to solar age. Table 1 provides an overview over the final sample. The literature overview of age, distance, and metallicity determinations is given in Table ?? in the Appendix. Membership probability histograms of the final sample are displayed in Figure ??.

2.3.1. Pleiades

118

128

129

146

147

148

The Pleiades, a nearby ZAMS cluster, were observed in Campaign 4, and were treated in PaperI. We include the cluster in this work for completeness and to illustrate improvements to (PaperI). We revisited the memberships from Rebull et al. (2016a), which were your in the previous work, and merged them with lists of members determined by Olivares et al. (2018); Gaia Collaboration et al. (2018a); and Cantat-Gaudin et al. (2018).

2.3.2. M35

M35 is a ZAMS cluster 900 pc away, observed during Campaign 0 in K2. We merged membership lists from Cantat-Gaudin et al. (2018); Gaia Collaboration et al. (2018a); and Bouy et al. (2015). There are only five K2 light curves, but we identified multiple additional members with publicly available light curves obtained from Soares-Furtado et al. (2017). They used an image subtraction technique in the campaign's super stamps, a self flat-fielding de-trending inspired by K2SFF (Vanderburg & Johnson 2014), and a trend-filtering algorithm developed by Kovács et al. (2005). We preferred PSF photometry in cases where both aperture K2 and PSF LCs were available. We took the raw extracted PSF light curves and de-trended them using K2SC.

2.3.3. Hyades

The Hyades are a 0.6 Gyr old OC observed during Campaigns 4 and 13 with K2. It is about as old as Praesepe. We merged membership tables obtained from Douglas et al. (2014); Reino et al. (2018); and Gaia Collaboration et al. (2018a).

- laboration et al. (2018a). 155

156 2.3.5. Ruprecht 147

Ruprecht 147 is a 2.5 Gyr old OC observed during Campaign 99 with K2. We used the mean membership probabilities obtained 157 158 from a number of studies (Curtis et al. 2013; Cantat-Gaudin et al. 2013) 159 2018; Olivares et al. 2019) combined with the members found 160

by Gaia Collaboration et al. (2018a) to identify the most likely 203 161

members. 162

2.3.6. M67 163

164

M67 is a solar-age, solar metallicity OC about 900 pc awans Multiple members were observed during Campaign 5, and 209 165 visited in Campaigns 16 and 18. We did not find any flareszing 166 M67 in Campaign 5 (PaperI) observing the members identified 167 by Gonzalez (2016). The recent campaigns brought both addig 168 tional observations, and entirely new targets to the sample. merged the members from Gonzalez (2016) with a recent sturby based of Gaia DR2 data (Gao 2018). Additionally, we obtained 171 172 PSF-detrended light curves for Campaign 5 from Nardiello et 246 173 (2016).

2.4. Effective temperatures, stellar radii, and luminosities

175 2.4.1. Photometry and extinction correction

We determined effective temperatures T_{eff} using broadbards 176 photometry the Two Micron All Sky Survey (2MASS; Skrutskie 177 et al. 2006), the Panoramic Survey Telescope and Rapid Re5 178 sponse System (Pan-STARRS) Data Release 1 (Chambers et 246 179 2016), and Gaia DR2 (Gaia Collaboration et al. 2018b). We 227 180 plied quality cuts to 2MASS, Pan-STARRS DR1, and GaiaD 228 181 data, as described in Appendix C, and removed foregroused stars using Gaia DR2 parallaxes. We corrected the 2MASS 183 and PanSTARRS photometry in M35, M67, and Ruprecht 184 147 for extinction using the most recent version (Green et 2d2) 185 2019) of the dustmaps package that provides 3D dust maps 186 derived from 2MASS and PanSTARRS photometry together 187 with Gaia distances (Green et al. 2018). If there was no Gabs 188 parallax available we used the cluster median distance inste2d6 189

If an extinction value was not available for a given star we used the average extinction value of the respective cluster. We accounted for extinction in Gaia BP and RP using the reddening $E(B_P - R_P)$ derived from Gaia photometry and parallax from Gaia DR2 (Andrae et al. 2018). We dropped targets that were too bright (Kepler magnitude $K_p \le 9$).

2.4.2. Effective temperatures

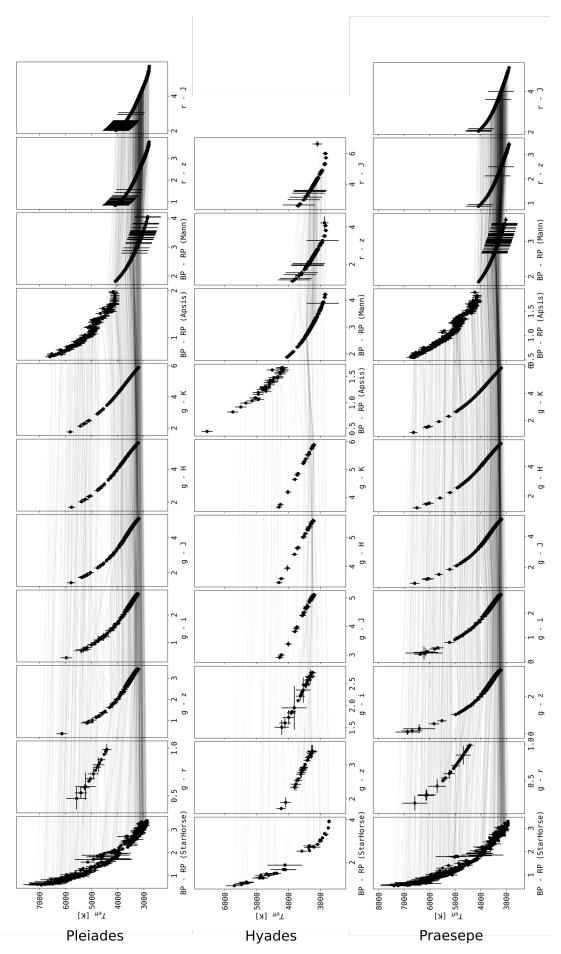

We applied several methods and color-temperature relations (CTRs) to determine robust T_{eff} . We used CTRs from Boyajian et al. (2013) and Mann et al. (2016) (erratum to Mann et al. 2015), and $T_{\rm eff}$ derived from Gaia DR2 using the StarHorse algorithm (Queiroz et al. 2018) and inferred from Gaia DR2 using the Apsis pipeline (Bailer-Jones et al. 2013; Andrae et al. 2018). Boyajian et al. (2013) determined CTRs from a range of interferometrically characterized stars using g - z, g - i, g - r, g - J, g - H, and g - K colors from SDSS and Johnson magnitudes for A to K stars. Their sample is centered on solar metallicity, so we constained the use of these CTRs to stars with -0.25 < [Fe/H] < 0.25. We transformed 2MASS JHK to J - H, H-K, and J-K in the Johnson system as the authors from 2MASS to the Bessell-Brett sytem (Carpenter 2001), and from Bessell-Brett to Johnson using the relations in Bessell & Brett (1988).

Mann et al. (2015) provide CTRs from absolutely calibrated spectra to which they fitted atmospheric models to obtain $T_{\rm eff}$. Alternatively, they determined $T_{\rm eff}$ from long-baseline optical interferometry measurements using the bolometric flux. Among others, they note transformations for SDSS/2MASS r - z and r - J, or Gaia BP - RP where extra information can be added from metallicity or 2MASS J - H. The relations in Mann et al. (2015) are only valid if metallicity is sufficiently close to solar, which is satisfied for all clusters in this paper (see Table ??). M35 may be an exception to this rule.

We supplemented our estimates with $T_{\rm eff}$ estimates from Anders et al. (2019) who used the StarHorse pipeline (Queiroz et al. 2018) on Gaia DR2.

Gaia DR2 published effective temperatures for over 160 million sources (Gaia Collaboration et al. 2018b). The typical uncertainty is quoted at 324 K, but it is lower for stars above ~4100 K and below ~6700K, so that we adopt 175 K which is above the quoted root-median-squared error in this $T_{\rm eff}$ range (Andrae et al. 2018), and use provided values only in this range.

Empirical CTRs suffer from systematic errors that stem both from the different methods applied, and from sample selection biases. We used as many empirical relations as possible in their appropriate ranges to obtain multiple $T_{\rm eff}$ estimates from which

we then drew a more reliable median value. Targets that were lacking sufficient photometric data to derive $T_{\rm eff}$, or were too last to be expected to have a convective envelope ($T_{\rm eff} \geq 7000; K$), were flagged accordingly, and removed from the sample. We dropped all targets where the uncertainty on the weighted mean

 $T_{\rm eff}$ was greater than 10%. Only targets that were assigned a $T_{\rm eff}$ were searched for flares.

237

238

239

240 241

312

323

324

244 2.4.3. Stellar radii

245 We used a catalog of empirically characterised stars (Yee et al. 2017) to derive R_* from T_{eff} (Fig. 4). Yee et al. (2017) collected 246 404 stars with high-resolution spectra from the literature, and 247 own observations of mid to late K-dwarfs, spanning low mass 248 stars from 7000 K down to 3000 K. For these stars, the resulting 249 250 catalog is accurate to 100 K in T_{eff} , 15 % in R_* , and 0.09 dex in [Fe/H]. We interpolated between stars from the catalog to our 251 252 derived $T_{\rm eff}$, and propagated the resulting scatter to the uncer-253 tainty in R_* if $T_{\text{eff}} > 3500$ K. For stars with $T_{\text{eff}} < 3500$ K we 254 used $T_{\rm eff}$ – R_* relations derived by (Mann et al. 2015, 2016).

2.4.4. Spectra

255

256 We assigned spectra to our targets from the SpecMatchEmp Yee 257 et al. (2017) and the FlareSpecPhot libraries (Schmidt 2014; 258 Kirkpatrick et al. 2010; Burgasser et al. 2007, 2008, 2010, 2004; Cruz et al. 2004; Burgasser & McElwain 2006; Rayner et al. 260 2009; Doi et al. 2010; Filippazzo et al. 2015; Cruz et al. 2003; West et al. 2011; Bochanski et al. 2010, 2007; Schmidt et al. 261 2010, 2015, 2014; Mann et al. 2015). When a specturm was 262 available for the derived spectral type in FlareSpecPhot, we pre-263 ferred it over SpecMatchEmp, which was the case for all stars 264 cooler than M0, where we mapped spectral type to effective tem-265 perature as appears in Pecaut & Mamajek (2013). We then com-266 bined stellar radii R_* , T_{eff} , and spectra to projected bolometric 267 luminosities $L_{\mathrm{bol},*}$, and projected luminosities in the Kepler band 268 $L_{\mathrm{Kp,*}}$ (Shibayama et al. 2013; Ilin et al. 2019). Uncertainties $\mathfrak{g}_{\mathfrak{p}}$ $L_{\mathrm{Kp,*}}$ ranged from 9 % to 52 % with a median value of 17 %.292

We detected flare candidates automatically, and validated the by eye. We attempted to assign recovery probabilities and c897 rected for sampling effects using injection/recovery tests but the procedure was not scalable due to computational costs. We performed injection recovery on a handful of example light curves to see that de-trending and intrinsic light curve properties smear out the ED recovery with varying distributions that add an uncertainty of the end of the tainty of about 30%. Most of the candidates are expected to have a complex shape that deviates from the classical flare templates The validation yielded an estimate on the uncertainty on the flare energy released in the Kepler band. The frequency distribution of these flare energies are believed to follow a power law tBQ5 spans multiple orders of magnitude. We adopted this model, and used two different Maximum Likelihood estimators to obtain and power law exponents. We tested the best fit parameters with \$108 Kolmogorov-Smirnov test, and probed possible truncation of and power law relation with an exceedance test. 310 311

3.1. Flare finding

We used the open source software AltaiPony² to automatically detect and characterize flares in our sample. The code base 165 lies on K2SC³ (Aigrain et al. 2016) to remove instrumental and astrophysical variablity from K2 light curves. We did not use the pre-detrended light curves available on MAST, but used K2SC³to derive our own, because we clipped outliers at $^{3}\sigma$ iteratively, $^{3}\sigma$ compared to the original work, where outliers were clipped $^{3}\sigma$ (Aigrain et al. 2016).

After de-trending, the flare finder algorithm looked for continuous observing periods, defined as being longer than 10 data points at a minimum cadence of 2 h. All further routines were run on these observing periods. The finder iteratively clipped excursions from the median value at 3σ rolling window noise above median plus uncertainty given from K2SC de-trending. After each iteration, outliers were cut down to the current median value. Either after convergence, or 50 iterations, the resulting median value was adopted. With this median as quiescent flux, flare candidates were identified with the same procedure as during the median value calculation, but now we additionally required at least three consecutive data points to fullfil the σ -criterion. Flare candidates were merged into single candidate events if they were no more than three data points apart. For each of these candidates occurrence time, amplitude and equivalent duration (ED) was returned.

The Kepler flare sample has shown to be difficult to treat in a fully automated way. Without manual vetting, the event samples remain significantly contaminated (Yang & Liu 2019).

ED is the area between the LC and the quiescent flux, that is, the integrated flare flux divided by the median quiescent flux F_0 of the star, integrated over the flare duration (Hunt-Walker et al. 2012):

$$ED = \int dt \frac{F_{flare}(t)}{F_0}.$$
 (1)

ED is a quantity independent of calibration and distance that is suited to compare flaring activity on stars where these properties are uncertain. It describes the time during which a star releases as much energy as the flare itself. This time can be shorter or longer than the actual flare duration.

The uncertainty in ED depends on the light curve noise properties, time sampling, and other intrinsic characteristics. Moreover, K2SC de-trending and the flare finding procedure introduce additional uncertainty that dominates the photometric noise. Carrying out injection and recovery that takes into account the effect of GP regression that underlies K2SC. We only performed injection-recovery on a small number of light curves with flares to estimate the .

3.2. Kepler flare energies

(see PaperI for details).

Multiband time resolved observations of active M dwarfs have shown that continuum flux accounts for the majority of the energy radiated by flares (Kowalski et al. 2013). The effective temperature of this blackbody, however, varies by a great degree, with, to date, no robust predictor of that temperature:

While solar flares are relatively $T_{\rm eff} \approx 5\,000 - 7\,000\,\mathrm{K}$ (Kleint et al. 2016; Kerr & Fletcher 2014; Watanabe et al. 2013; Namekata et al. 2017), SEDs of stellar flares tend to be blue (?). At least one M dwarf flare reached 40 000 K as seen in FUV spectra (Froning et al. 2019), and most events exhibit temperatures of about 9000 – 10000 K (Hawley & Fisher 1992; Kretzschmar 2011; Shibayama et al. 2013). A dependence of flare temperature on stellar age, or mass, or both, will enter our analysis if we attempt to quantify bolometric flare energy. At about 6 200 K, the Kepler pass band captures the largest flux fraction, at 10000 K 72%, at 40 000 K only 4% of this value is transmitted. Another effect is that flares of equal flare energy but hotter SED would not be seen in the Kepler band at all.

We propagated the uncertainties σ_{ED} and σ_{L} (on $L_{*,Kp}$) in

3.3. Power law fits

Flare frequency distributions follow power law relations that cover several orders of magnitude, from solar microflares to start lar superflares. We fitted power law functions to the FFDs us three different approaches.

The first method was a maximum likelihood estima 884 (Maschberger & Kroupa 2009). As recommended (MLE) by Maschberger & Kroupa (2009), we applied the stabilizes Kolmogorov-Smirnov (KS) test at 95 % significance level to 387 power law fits in the sample. If the test fails the power law modes does not fit the data at the given significance level. If the test passes, this does not give any information whether the power law model is the correct assumption. The goodness of fit can be estimated from the visual inspection of percentile-percentile plots, given in the online material⁴. We used the KS test ite 293 tively to determine the FFDs' low-energy cutoff EDmin for fixed power law distribution. This cutoff does not reflect the physials threshold for criticality because the cutoff is seen at lower en 296 gies in similar stars with higher sensitivity, for example, higher candence. The cutoff also does not directly imply that flare can also does not directly imply that flare can be caused as a constant of the cutoff also does not directly imply that flare can be caused as a constant of the cutoff also does not directly imply that flare can be caused as a constant of the cutoff also does not directly imply that flare can be caused as a constant of the cutoff also does not directly imply that flare can be caused as a constant of the cutoff also does not directly imply that flare can be caused as a constant of the cutoff also does not directly imply that flare can be caused as a constant of the cutoff also does not directly imply that flare can be caused as a constant of the cutoff also does not directly imply that flare can be caused as a constant of the cutoff also does not directly imply that flare can be caused as a constant of the cutoff also does not directly imply that flare can be caused as a constant of the cutoff also does not directly imply that flare can be caused as a constant of the cutoff also does not directly imply that the cutoff also does not directly imply the cutoff also does not directly imply the cutoff also does not dir didates detected above or below the cutoff are more or less likepy to be detected because the flare detection probability is a furfloo tion of both duration and amplitude, and not only of energy! Above all, it is not straighforward to account for the deviation? from an ideal power law at low energies, because the aforemend tioned effects may be partly cancelled by background conta 404 ination from, for instace, cosmic rays (?). We believe that 405 are mostly limited by the non-linear dependence for the energe bias from time sampling effects (?) and recovery probability 497 flare duration and amplitude. These parameters are not resolved in FFDs, and while they are correleted there is significant spretted in the duration-amplitude relation to blur the cutoff in the FPD? One way to account for this circumstance is to inject and reco synthetic flares with a variety of durations and amplitudes and 469 determine energy ratios and recovery probabilities for each 11/13 dividual candidate, assuming that the underlying flare shape call be sufficiently well parametrized, as was done in Davenport et 415

The second method used the MLE result as a prior for α . Follow ing Wheatland (2004), we defined the joint posterior distribution for the probability ϵ that a flare with ED or energy above some value S_2 occurs within a time period ΔT :

$$p(\epsilon, \alpha) = C \cdot (-\ln(1 - \epsilon)^{M})$$

$$\cdot (\alpha - 1)^{M} \cdot \Gamma(\alpha) \left[\frac{(S_{2}/S_{1})^{M+1}}{\pi} \right]^{\alpha}$$

$$\cdot (1 - \epsilon)^{(T/\Delta T) \cdot (S_{2}/S_{1})^{\alpha-1} - 1}.$$

$$421$$

$$423$$

$$423$$

369 C is the normalisation constant, M is the number of events,4**7**5 the total observation time. Γ contains the prior distribution for 4**2**6 and S_1 denotes the detection threshold above which all flares 4**2**7 detected. π encapsulates the flare energies as

$$\pi = \prod_{i=1}^{M} \frac{s_i}{S_1}$$
 428 (3) 429

373 , where $\{s_1, s_2, ... s_m\}$ are the flare energies or ED.

The posterior distribution in Wheatland (2004) captures both $\frac{431}{432}$

the Poissonian distribution of flare events in time, and their power law distribution in energy, simultanesously. Wheatland (2004) derived this model to be able to predict the flaring rate of a given active region on the sun, and offered an extension to Eq. 2 that treated changing flaring activity rates as the active region evolves, and also characteristics of the active region itself, such as sunspot classifiers. In our simplification of the model, we assumed that the flare generating process did not change within the observation time span in any star in our sample (M = M' in Eq. 24 in Wheatland (2004)). Another assumption was that this process was the same for all stars in the sample ($\Lambda_{MC} = 1$ in Eq. 24). Under these assuptions the information gained from the light curves could be stacked together.

With a uniform prior for α the results from the MLE and Markov Chain Monte Carlo (MCMC) sampling from the posterior distribution are the same, the latter allowed us to fit for ϵ and α simultaneously. Another advantage of the latter approach is that we could use more informative priors.

We chose our prior to reflect the power law exponent results discussed in the literature. The studies we took into account analysed flare frequency distributions of stellar flares in the optical regime, and focused mostly on K and M dwarfs (Lurie et al. 2015; Howard et al. 2019a; ?; ?) or ultra-cool dwarfs (?) but also solar-type stars (Shibayama et al. 2013). We also used a Gaussian fit to α obtained from the posterior distribution using the full sample of flares as the prior for a subsequent Bayesian analysis of individual age and $T_{\rm eff}$ bins. Assuming that α is universal for all spectral types, ages, and flare energy ranges, we used this more informative, Gaussian prior to further constrain the flaring rates.

Additionally we calculated the exceedance statistic tr to test if the power law distribution was truncated. If tr is 1, the power law distribution is truncated at the high energy end. If tr is 0, no information was gained from the calculation. To derive tr, given a number n of observations X_n and a best fit value for the power law exponent, we generated 500 samples with nvalues from this best-fit distribution assuming no truncation, i.e. choosing an upper limit several orders of magnitude higher than X_{max} . We then proceeded to truncate the samples at thresholds T below the maximum observed value X_{max} and determined the average number N_{ex} of generated values that will exceed T. If the underlying power law is not truncated, N_{ex} declines with larger n, as larger X_{max} will be present in the original data. If the best fit power law exponent is steeper, N_{ex} will be underestimated. If the best fit power law exponent is flatter, N_{ex} will be overestimated. If the power law is not truncated, for $n > 100 N_{ex}/n$ will be < 5%, for 20 < n < 100, typically $N_{ex}/n < 15\%$.

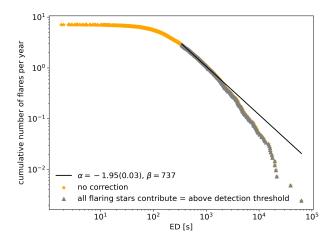

4. Results

430

Fig. ?? shows the $E_{\rm Kp,flare}$ and ED detection thresholds, as defined by the recovery probability (see Sec. ??). The thresholds in ED reflect the noise level in the light curves.

4.1. Flaring activity as a function of a age and $T_{\rm eff}$

Flaring activity decays with age. Flaring fraction was observed to decline with galactic latitude for M dwarfs (Hilton et al. 2010)Howard+2019. Short rotation periods and high magnetic activity measured in H α are strongly correlated (West et al. 2015). According to gyrochronology, fast rotation indicates young age (Barnes 2003), and slows down as the star ages. Here,

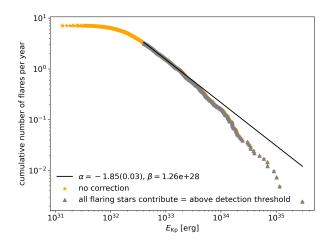

Fig. 5. FFD (scatter) in ED (left panel) and energy (right panel) and respective power law fit (black line) to the full sample of flare candidates.

480

481

485

4.2. M67 and Rup 147

We found several flare candidates in stars that are members 466 M67 and Rup 147. However, all but the events that occurred 467 four stars were false postives (SSOs), or the stars were not singto members. Flare candidates in these old clusters appeared on RS9 CVn binaries, cataclysmic binaries, Algol type binaries, spect#30 scopic and eclipsing bianries, and red giant stars. Excluding 411 these, we were left with one flare in M67 on a K1 dwarf. In R47/32 147, we narrowed down the list to a flare on a G8 star in R473 147, and four flares each on a K0.5 and an M3 star. For these stars, the multiplicity status is unknown. We found that the mass. range of these stars as calculated from the uncertainties on the 76 radii (?) is large enough that the stars could in principle be binary 478 stars with undetected mid-M dwarf companions. 479

4.3. Flaring Activity Indicators

Flaring rates: FR and flaring fraction We define FR as the flare 457 rate above detection thresholds on $E_{\text{Kp,flare}}$ and ED in each f_{eff}^{183} 458 459

bin, respectively (Figs. ?? and ??).

Flaring energy: FA and $L_{\mathrm{Kp,flare}}$ The energy released in flarest was inferred using our derived stellar luminosities. It declines with age for every $T_{\rm eff}$ bin considered for both the total lumin 489 ity and relative to the quiescent flux (Fig. ??).

 $L_{\rm Kp,flare}$ is the luminosity in flares in the Kepler band. We can relate this to the quiescent bolometric luminosity of the star when we define the fractional flare luminosity FA as in PaperI:

$$FA = \frac{1}{N} \sum_{i}^{N} FA_{i} = \frac{1}{N} \sum_{i}^{N} \frac{E_{\text{Kp,flare,tot},i}}{t_{i} \cdot L_{\text{bol},*,i}}$$
(4)

We determine $L_{\text{bol},*}$ from R_* and T_{eff} , as described in Sec. 2.4. This is a meaningful measure of relative stellar activity as long as only the flux portion of the quiescent star in the Kepler band is roughly constant. It is therefore sensible to compare FA values across ages, but not across $T_{\rm eff}$.

FFD Power law fit parameters to the FFDs (Figs. ?? and ??) are sensitive to the low-energy cutoff, where most observations reside. The goodness of fit strongly depends on the sample size. Power law fit parameters derived using MLEs, as described in Sec. 3.3, are mostly consistent with each other but often deviate from $\alpha = 2$. A smaller sample size tends to create a flatter distribution (Figs. 7 and ??). Truncation was not detected for FFDs with more than 50 flares (Tables ?? and ??) For these results, extrapolations outside of the observed energy range are clearly off. If we assume $\alpha \equiv 2$, different distributions can be compared. For fixed α , in the ED domain, β_2 is the flare frequency at ED = 1 s, and shows a trend in both $T_{\rm eff}$, and age (see Fig. ??). In the energy domain, the picture is less clear (Fig. ??).

Compare to other FFD values, e.g., from Ward's Evryscope survey, see table in Appendix, and maybe convert it to a plot Howard et al (2019) monitored superflares on cool stars with bolometric energies above 10^{33} erg and up to 10^{36} erg. They find power law exponent values around ~ 2 resolved by spectral types. Similar values are found for individual flare stars (Lurie et al. 2015). Howard+18, Loyd+18, Tilley+19 show that flares can erode exoplanetary atmospheres. If a flare is assumed to deposit its UV energy in an instant a single superflare can completely remove

the ozone layer at the substellar point Loyd+18. Associated protons are safer way to ozone destruction if they are associated with reoccurring large flares Tilley+19

494

495

491 5.1. Consistency with other studies

492 EvryFlare, mass-dependence,

5.2. Flaring and rotation

More energetic flares can be expected from faster rotational stars (Candelaresi et al. 2014; Doorsselaere et al. 2017; Yang

et al. 2017). Findings that flares with intermediate Rossby number appear to flare more than fast and slow rotators (Mondrik et al. 2019) could not be reproduced here or in the EvryFlare survey (Howard et al. 2019b). If enhanced flaring can be interpreted as an increase in the stellar angular momentum loss rate flaring activity can be used to inform the cause of variation in the spin-down efficiency. An example of such variations is the apparent temporary stalling of spin-down seen in K dwarfs in NGC 6811 (Curtis+2019). The authors favored a scenario in which

586

the stellar core transfers momentum onto the envelope but did not rule out the possibility of a decreased magnetic braking entire the possibility of a decreased magnetic braking entire transfers. 505 506 ciency. In the latter scenario, these stars should flare less. We used rotation periods derived from K2 light curves for the 508 Pleiades (Rebull et al. 2016b), the Hyades (Douglas et al. 2016), and Prassana (Pabull et al. 2017), to illuminate the rotation 509 and Praesepe (Rebull et al. 2017), to illuminate the rotation 510 flaring relation at fixed ages. In the Pleiades, most flaring start 511 are found on the fast rotator branch at or below one day, $a\underline{\underline{n}}\underline{d}$ 512 flaring activity peaks in this regime. For Praesepe, flaring $ra_{\underline{tes}}^{570}$ 513 aappear t ..[...]. In the Hyades, all of the 11 stars with rotation 514 periods that overlapped with our sample were found flaring, but 515 the number were too low to provide statistical insight. For Rup 147, M35 and M67, no rotation rates were available at the timera

520

521

522

523

524

526

527

528

529

530

Comparing our results to a similar study of photometric flages in M37 (Chang et al. 2015) we find the results somewhat discrepant. M37 is 300-600 Myr old and appears less active that Praesepe and Hyades in individual Teff bins, which are of coe \$\frac{547}{647}\$ or older. We attribute the difference to the loose membership \$\frac{7}{648}\$ quirement of \$pmem \geq 0.2\$ in Chang et al. (2015) as compared our stricter cuts at 0.8. We expect the M37 to be contaminated with field stars that systematically reduce the flaring rates. A\(\frac{7}{647}\) plying our own restriction the M37 sample (Chang et al. 20 \$\frac{7}{647}\) leaves very few flares that hamper a statistical description of the distributions.

5.4. Division at 3000 K

The lowest T_{eff} bin at Pleiades age in our sample reflects the 531 division between fully convective stars and those with a radia-532 tive core (Reid & Hawley 2005). At this age, the coolest dwaffs 533 may still be accreting angular momentum on the PMS, instead 534 of spinning down on the MS. We suggest that a regime change 535 occurs around 120 Myr for stars with $T_{\text{eff}} = 2500 - 3250 \text{ K}$. ⁵⁹¹ 536 Below 3000 K, an analysis of 66 ZDI maps show that magnetic 537 field configurations can be strong and dipolar or weak and mand man and man and man and man are strong and dipolar or weak and dipolar or weak are strong are strong and dipolar or weak are 538 tipolar (Morin et al. 2008; See et al. 2017). If these stars can be 539 distinguished by age, this should be reflected in our age-resolved 540 flaring activity. If the difference is not a function of age, we 541 should see a similar bimodal distribution of very inactive asset 542 very active stars in the lowest mass bins. If the difference 506 543 tween the two configurations is a function of age, we should one 544 see one type of stars with correspondingly similar behaviour598 545 these $T_{\rm eff}$ bins. 546

The lowest mass bin appears underactive compared to the rest**600** the flaring-age- $T_{\rm eff}$ relation in the ED domain. Physical expla**604** tions for this peculiarity include: A different magnetic struct**1602** A truncation of the power law that reflects the maximum ED**603** active region can produce on these stars. 604 West et al. (2015) found that all M1-M4 dwarfs with rotation **1605**

riods shorter than 26 days, and all M5-M8 dwarfs with periods shorter than 86 days show $H\alpha$ emission, indicating their magnetic activity.

Assuming a typical binary fraction for early and mid M dwarfs (Fischer & Marcy 1992), we can expect some of the flares on stars at $T_{\rm eff} > 3000$ K to belong to unresolved binary companions with $T_{\rm eff} < 3000$ K. A misattributed flare on an early M dwarf then will be assigned a too small ED, but still a correct $E_{\rm Kp,flare}$ because the count ratios are equal to the $L_{\rm Kp}$ ratios.

5.5. Consistency of Hyades' and Praesepe's results

HRDs constructed in Gaia Collaboration et al. (2018a) indicate only slightly older ages for Hyades and Praesepe. We expect our results to reflect this similarity.

Are the samples comparable? Membership determination may differ. Can we frame this as a statistical test, i.e. answer the question: What is the probability that the activity distributions for both clusters were drawn from the same underlying distribution for a given age and mass bin?

Metallicity is controlled for ([Fe/H](Praesepe) = 0.16, [Fe/H](Hyades) = 0.13, Netopil et al. 2016).

5.6. Consistency of Pleiades and M35 results

M35 is has subsolar metallicity, while Pleiades are roughly solar.

5.7. Jim's section(s)

Flaring activity function of mass and age – a gyrochronology analog?

Results in the context of Davenport et al. (2019): How well does the model fit if we have isochronal and not rotational ages for our stars?

Davenport et al. (2019) note a sample bias towards more active stars. Their models overpredicts the superflaring rate of the average Sun-like sample from Shibayama et al. (2013) and more resembles the rate for their most active sub-sample. Do we see the same effect in our OC sample? We should not. Or cluster memberships depend on activity.

5.8. Universality of α

Takin into account uncertainties and systematic errors resulting power law fitting methods, the power law exponent $\alpha \sim 2$ appears to be the same for all studies on flare statistics so far, irrespective of spectral type. A noteable exception are A stars in Kepler that follow a power law with $\alpha \sim 1$ that may indicate a different physical process (Yang & Liu 2019).

5.9. Deviations from single power law

Spots can survive on the stellar surface from a few days to nearly a year (Namekata et al. 2017; Davenport 2015). Namekata et al. (2017) find conceivable that spots evolve on timescale shorter than the estimated lifetimes. Complex spot geometry is correlated with the stongest X-class flares on the Sun (Toriumi et al. 2017; Sammis et al. 2000). This support the idea that flares are associated with the presence of certain types of starspots, or more generally, certain types of active regions. Since we can reasonable expect that there is a maximum flare energy a spot can produce, the underlying power law relation must break a some $ED_{\rm max}$. We tested a possible truncation of our FFDs, but find no

675 676

677

678

conclusive evidence for it in any FFD with > 50 data points. 606 we stack multiple targets, each potentially with multiple, evo 607 ing spots of various sizes on their surfaces, into one FFD at a 608 time, we might observe a deviation but no truncation. A differ-609 ent explanation is simply that we do not sample the maximum 610 energies, as extremely high relative fluxes have been observed in 611 the past (Paudel et al. 2018; Jackman et al. 2019; Schmidt et $\frac{642}{673}$ 612

6. Summary and Conclusions

613

614

615

651

665

667

668

2016).

Is there or will be there more data available to further extend the sample? There are no model-independent stellar ages. It is more 616 correct to speak of evolutionary stage. Stars in open clusters with 617 precise isochronal ages have their observables reduced to a number 1884 618 ber of years. We can now ask: Can we unambiguously map flast. ing evolutionary stage to the evolutionary stage of isochronal 620 parameters of a given star? If there is either a strong correlation? 621 or even a physical relation between flaring activity and, for $\frac{688}{689}$ 622 stance, mass and rotation rate, the answer is yes. If this relation 623 is sufficiently sensitive to be captured by present day instrument 624 tation, and non-degenerate in the relevant parameters, flaring 602 625 tivity can be integrated into the family of age indicators, and 626 complement and extend them.

627 628 Ultimately, flaring activity depends on how efficiently the stars converts its energy budget to flares throughout its lifetime. Singer the fraction of total luminosity released in flares is small every for the most active stars, this efficiency need not scale directly with the overall energy budget of the star on the MS, but will 632 more likely depend on the ability of the star to use this budget 633 flaring.

to produce magnetic surface topologies and strengths that enable 634 635 A magnetic dynamo, driven by rotation and convection, intro 636 duces magnetic field to the system that causes stellar wind that 637 in turn removes angular momentum from the star, decreasing 708 638 rotation rate. Over time, the wind takes away more and more $\frac{709}{100}$ 639 gular momentum, and the global magnetic field weakens. This is reflected in observations of chromospheric indicators (ZDI???)2 641 The decline is famously known as the Skumanich law, and gates 642 rise to the rotational age-dating technique called gyrochron 514 643 ogy. However, recent studies noted deviations from this rule 718 644 stalling of the spin-down, and offered multiple competing ex-645 planations. It is not clear how these effects reflect on the small 646 scale surface magnetic field. Chromospheric activity on sold? 647 type stars seems to continue to decline regardless of these $\frac{160}{21}$ 648 tational effects. 649 What about X-ray? 650

scale topology of stellar magnetic fields beyond extrapolations 652 from the solar case. On the Sun, chromospheric activity indicates 653 line emission in excess of radiative equilibrium that is caused to 654 magnetic fields. Likewise, magnetic field effects heat the coro 655 656 Acknowledgements. This work made use of the gaia-kepler.fun crossma 781 657 database created by Megan Bedell. Appendix A: Membership probabilities

828 To match catalogs on RA and declination we used \$68 829 astroML.crossmatch tool for Python (Vanderplas et al. 201259 830 For the studies with classifiers we assigned membership pro1860 831 bilities as follows. In Gonzalez (2016):

863 p(M(member)) = 0.9,864 p(BM(binary member)) = 0.9,865 0.1,p(N(non-member)) =866 p(SN(single non-member)) =0.1,867 868 p(BN(binary non-member)) =0.1,869 p(U(unknown member)) = 0.5.870

832 In Curtis et al. (2013):

827

p(Y(highest confidence member)) = 0.9, p(P(possible/probable member)) = 0.7,p(N(not likely/non-member)) = 0.7,

p(B(photometry consistent with blue stragglers)) = 0.0.

833 In Rebull et al. (2017):

p((best)) = 0.9, p((ok)) = 0.6,p((else)) = 0.1.

Members from Rebull et al. (2016a); Douglas et al. (2017); and Gaia Collaboration et al. (2018a) were assigned p = 0.9 if the same appeared in the final catalog.

Table A.1 gives an overview over different membership catalogs Figure A.1 shows membership probability histograms of the sample broken down by membership source. Detailed intress tions on how to reproduce the final sample of members in each cluster, and corresponding tables, Python scripts, and Jupyter

842 notebooks can be found online⁵

844

845

853

843 Appendix B: Cluster parameters

Appendix C: Broadband photometry: quality cuts 885 and conversions

846 We required flux/flux_error \geq 10 for Gaia G, BP, and RP 847 bands. We require that the 2MASS measurements for J, H, and 848 K to be "A". "A" means that measurements had S/N > 10 and 849 $\sigma < 0.11$. For PanSTARRS photometry, we required that the

oro OF ORI COOR quality filter flow was not

850 QF_OBJ_GOOD quality filter flag was set.

851 SDSS and PS1 *ugrizy* bands are similar but not identical, but can

be converted using Table 2 in Finkbeiner et al. (2016).

Appendix D: Pixel saturation

Resolve different levels of pixel saturation (>1, >10) and half they contribute to the deviations from the single power law the highest energies.

Article number, page 16 of 20

Appendix E: Solar system objects

Solar system objects (SSOs) produce brightness excursions in K2 light curves that can closely resemble flare signatures. Often, they can be distinguished by their symmetric rise and decay shape as contrasted with the typical fast-rise gradual decay flare shape (Davenport et al. 2014). M. H. Christiansen and colleagues developed a routine called SkyBoT that matches positions and times to passages of SSOs listed in YYY. RA, declination, start, stop, and mid epochs of flares in BKJD are the input parameters. We excluded all flare candidates that occurred within X minutes of a SSO passage at the star's position. This procedure removed ZZ% of all flare candidates. In the case of high energy flares, we confirmed the passage by manually inspecting the pixel file with the lightkurve interact function for TargetPixelFiles.

Appendix F: Universality of power law exponent α

We compiled a exhaustive (?) table of previous work where power laws were fitted to FFDs using different methods. Table F.1 lists the overview. While particular studies consistently find values above or below $\alpha \approx 2$, the comparison of different studies points towards unresolved systematic errors in all these studies.

Appendix G: Expanding the likelihood

The rate λ_2 of flares with energies larger than S_2 is given in Wheatland (2004) as

$$\lambda_2 = \lambda_1 \cdot \left(\frac{S_1}{S_2}\right)^{\alpha - 1}.\tag{G.1}$$

 S_1 denotes the energy above which all flares are detected. λ_1 is the corresponding rate. α remains the power law exponent of the flare frequency distribution.

We are also given the posterior distribution for the rate λ_2 of flares above S_2 in Eq. (20) in Wheatland (2004):

$$P_{2}(\lambda_{2}) = \int_{1}^{\infty} d\alpha \int_{0}^{\infty} d\lambda_{1} \delta \left(\lambda_{2} - \lambda_{1} \cdot \left(\frac{S_{1}}{S_{2}} \right)^{\alpha - 1} \right)$$

$$\cdot P_{1}(\lambda_{1}) \cdot P_{\alpha}(\alpha)$$
(G.2)

As we have additional information in the form of uncertainties in our data $S = \{S_i, \lambda_i, \sigma_{S,i}\}$, we can expand Eq. G.2 with this knowledge. Assuming that the observed flare energies S_i with cumulative rates λ_i are distributed around the real flare energies $S_{0,i}$ with Gaussian uncertainties $\sigma_{S,i}$, we can define:

$$p(S_i|\lambda_1, \alpha, \sigma_{S,i}) = \frac{1}{2\pi\sqrt{\sigma_{S,i}}} e^{-\frac{\left(S_i - S_{0,i}\right)^2}{2\sigma_{S,i}^2}}$$

$$= \frac{1}{2\pi\sqrt{\sigma_{S,i}}} e^{-\frac{\left(S_i - S_1\left(\frac{\lambda_i}{\lambda_1}\right)^{-1/(\alpha-1)}\right)^2}{2\sigma_{S,i}^2}}$$

$$= \frac{1}{2\pi\sqrt{\sigma_{S,i}}} e^{-\frac{\left(S_i - S_1\left(\frac{\lambda_i}{\lambda_1}\right)^{-1/(\alpha-1)}\right)^2}{2\sigma_{S,i}^2}}$$
(G.3)

We assume in Eq. G.3 that uncertainties on λ_1 are negligible. Eq. G.2 then reads:

$$P_{2}(\lambda_{2}) = \int_{1}^{\infty} d\alpha \int_{0}^{\infty} d\lambda_{1} \delta \left(\lambda_{2} - \lambda_{1} \cdot \left(\frac{S_{1}}{S_{2}} \right)^{\alpha - 1} \right)$$

$$\cdot P_{1}(\lambda_{1}) \cdot P_{\alpha}(\alpha) \cdot P_{S}(S|\lambda_{1}, \alpha, \sigma_{S})$$
(G.4)

with

$$P_{S}(S|\lambda_{1},\alpha,\sigma_{S}) = C \prod_{i=1}^{M} p(S_{i}|\lambda_{1},\alpha,\sigma_{S,i}).$$
 (G.5)

- 890 C absorbs the normalization, or evidence term.
- Following Wheatland (2004), we marginalize over λ_1 using the
- 892 δ function in G.4 to obtain

$$P_{2}(\lambda_{2}) = \int_{1}^{\infty} d\alpha \cdot P_{1} \left(\lambda_{2} \cdot \left(\frac{S_{2}}{S_{1}} \right)^{\alpha - 1} \right) \cdot P_{\alpha}(\alpha)$$

$$\cdot P_{S} \left(S | \lambda_{2} \cdot \left(\frac{S_{2}}{S_{1}} \right)^{\alpha - 1}, \alpha, \sigma_{S} \right)$$
(G.6)

- 893 Transforming P_S into a function of ϵ with $\lambda_1 = -\ln(1 \epsilon)/\Delta T$
- 894 yields:

$$P_{S}(S|\epsilon,\alpha,\sigma_{S}) = C \prod_{i=1}^{M} p(S_{i}|\epsilon,\alpha,\sigma_{S,i})$$

$$= \frac{C}{\Delta T(1-\epsilon)}$$

$$\cdot \prod_{i=1}^{M} \left[\frac{1}{2\pi \sqrt{\sigma_{S,i}}} e^{-\frac{\left(S_{i} - S_{2}\left(\frac{-\ln(1-\epsilon)}{\Delta T \lambda_{i}}\right)^{1/(\alpha-1)}\right)^{2}}{2\sigma_{S,i}^{2}}} \right]$$
(G.7)

895 Finally, P_S enters the joint posterior distribution from Eq. 2, that

896 becomes

$$p(\epsilon, \alpha) = C \cdot (-\ln(1 - \epsilon)^{M})$$

$$\cdot (\alpha - 1)^{M} \cdot \Gamma(\alpha) \left[\frac{(S_{2}/S_{1})^{M+1}}{\pi} \right]^{\alpha}$$

$$\cdot (1 - \epsilon)^{(T/\Delta T) \cdot (S_{2}/S_{1})^{\alpha-1} - 1}$$

$$\cdot P_{S}(S|\epsilon, \alpha, \sigma_{S}). \tag{G.8}$$

Praesepe	Scholz et al. (2015)	187	832	
Praesepe	Boesgaard et al. (2013)	4.50		0.12
Praesepe	Boudreault et al. (2012)	160	630	
Praesepe	Salaris et al. (2004)	175	650	0.00
Rup 147	adopted in this work:	305	$2650\pm_{380}^{380}$	0.08 ± 0.07
Rup 147	Bragaglia et al. (2018)	205		0.08 ± 0.07
Rup 147	Cantat-Gaudin et al. (2018)	305	1005 : 404	
Rup 147	Gaia Collaboration (2018)	309	$1995\pm_{257}^{404}$	
Rup 147	Torres et al. (2018)	283	$2650\pm_{380}^{380}$	0.40
Rup 147	Curtis $(2016)^b$	270	1072	0.10 ± 0.02
Rup 147	Scholz et al. (2015)	270	1953	0.05
Rup 147	Curtis et al. (2013)	300	$3125\pm_{125}^{125}$	0.07 ± 0.03
M67	adopted in this work:	908	3639±17	$-0.102 \pm .081$
M67	Bossini et al. (2019)		$3639\pm^{17}_{17}$ $3639\pm^{17}_{17}$	
M67	Netopil et al. (2016)		1.47	0.03
M67	Scholz et al. (2015)		$3428\pm_{72}^{147}$	
M67	Conrad et al. (2014)	000	1200	$-0.102 \pm .081$
M67	Dias et al. (2012)	908	4300	0.00
M67	Onehag et al. (2011)	880	4200	0.02

Notes. ^(a) Bossini et al. (2019) noted some caveats for their determination of ages of young clusters, for which they used Gaia DR2 photometry for isochrone fitting. ^(b) Curtis (2016) reanalysed HIRES spectra using an improved spectroscopic method as compared to Curtis et al. (2013). ^(c) We did not adopt a mean value for the Hyades distance because the cluster members are on average closer than 50 pc.

Table F.1. Literature overview over power law fitting approaches to FFDs.

Who	method	data	α – 1
Hawley et al. (2014)	LSq with Poisson uncertainty, increase the low energy limit until the fit is robust		.95 (binned), 1.01 (cumulative)
Davenport (2016)	weighted LSq, asymmetric Poisson confidence intervals following Gehrels1986		
Gizis (2017)	de-biased MLE (Arnold2015), weight each point with sqrt(N) in each bin (Clauset+2009	22 flares on one M7 UCD	.6-1. (31-33 erg)
Paudel et al. (2018)	ML from a paper in 2010, used emcee (Foreman-Mackey2013)		
Lacy (1976) Güdel et al.(2003)	graphical, linear LSq	386 flares on UV Cetis	.43-1.
Davenport et al. (2012)	Fit $\log_{10} Y = \alpha + (\beta \log_{10} X)(10 - \gamma/(X + \delta))$	~50,000 M dwarfs from SDSS and 1321 M dwarfs from 2MASS	.9-2.1
Lurie et al. (2015)	Bayesian Markov chain Monte Carlo based algorithm (Kelly 2007) for linear regression	2 dMe5 dwarfs	.92-1.03
Audard et al. (2000)	Crawford+1970 MLE (Jauncey-style)	EUVE 12 F-M type stars, 10-20 flares each	.46-1.61
Shakhovskaia (1989)	linear representation, power laws from Gershberg/Shakhovskaya1983	30-40 dK0-dM8, 200 flares	.4-1.4
Yang et al. (2017)	binned FFDs	103187 flares on 540 M-type dwarfs in Kepler	1.07 +/- 0.35
Howard et al. (2018)	fit a cumulative power law, MCMC for uncertainties	575 flares on 284 stars	0.84-1.34
Hilton et al. (2011)			.6383
